In the mean time the other sciences had been revived and with them also the study of antiquity, which gave a different turn to the study of geography during the 17th century. Many persons well informed in ancient history visited Greece and the countries of Western Asia, with the view of examining those parts which had once been the theatre of great events. Such *historical* travellers were very numerous during the second half of the 17th and the first half of the 18th century; and though at first they confined their researches chiefly to such places as had obtained some historical celebrity, they afterwards extended their views to the physical character of the countries in which such places were situated, and gave us some excellent descriptions of them, such as we find in the travels of Chardin, Shaw, Pococke, Chandler, and Carsten Niebuhr. These travels greatly contributed to the improvement of geography as a science. They brought history and geography again into close connection. Before this time geographical works contained hardly anything beyond a dry catalogue of names of places, rivers, and political divisions. But in describing the still existing ruins of places celebrated in ancient history geographers were compelled to go back to those ancient authors who had treated of these places, and thus a part at least of the geographical knowledge of Herodotus, Polybius, and Strabo, was transplanted into our modern geographical treatises. Thus a great deal of very interesting and useful matter found its way into treatises on geography, which had hitherto been entirely excluded, partly because it had not been known, and partly because it had been considered as foreign to the object of the science. If any person will take the trouble to examine any of the geographical works of the middle of the 17th and 18th centuries, he will find that more than three parts out of four of their contents have changed in the course of 100 years.

Still the science of geography remained in a very imperfect state. Only a few spots in each country had been described with any degree of precision. The peculiar character of an entire country, and of its component parts, had never been made a subject of inquiry. It had never been a subject of investigation, how far the physical character of a country was favourable or adverse to the civilisation of its inhabitants. This has now in a great degree been effected by the naturalists and other men of science, who during the last and the present century have visited nearly every part of the globe. In course of time the researches of travellers and voyagers have thus been extended to a greater number of new objects. At first they limited their labours to the extension of Natural History, adding a few observations on the countries through which they passed. Thus Tournefort, who travelled through Asia Minor, Armenia, and Persia, may be considered as the first travelling naturalist. But by examining the natural productions of a country, travellers were insensibly led to an investigation of their climate. In their attempts to establish the mean temperature of different places, and its effects on vegetation and animal life, they soon perceived the great influence which a variation in elevation above the level of the sea has on both. Thus they gradually learned that nearly every country is divided by nature into a smaller or greater number of parts materially differing in climate and natural productions. The knowledge of this fact mainly contributed to give geography a new character, and to introduce new and important elements into the geographical descriptions of countries, such as we find in the works of Pallas, Dr. Francis Buchanan Hamilton, and Alexander von Humboldt. What these great men, and several of their less distinguished predecessors, did, and what their eminent successors, such as Dr. Bebe, Prof. James Forbes, Dr. Thomas Thomson, Dr. Joseph D. Hooker, Mr. A. R. Wallace, and others, have continued to do, for the countries out of Europe, has been accomplished with equal success for the European continent by the labours of numerous excellent writers.

Geography, then, in its present state, and in its practical application, has for its object the determination of all those facts, as to any given country, which will enable us to judge of its fitness to provide man with food, and to promote his civilisation. As a science, its object is to deduce, from all the observed phenomena within its sphere, those general principles which enable us from certain known facts, as to any given country, to infer others not ascertained, and which indicate what are, as to each portion of the earth, the proper objects of inquiry. It is not every part of a country that possesses equal advantages for the habitation of man. Some parts are more favoured by soil and climate than others. There are also tracts which are inferior in both respects, but by the aid of other advantages, especially those of easy communication, have risen to a higher degree of prosperity and cultivation than many others in their neighbourhood which are more favoured in soil and climate. No correct knowledge of a country can be acquired unless the parts of it which are distinguished by their natural advantages or disadvantages are separated from each other, and unless a particular description is given of each, with its extent, and the proportion which it bears to the whole country. The first business of the geographer then must be to make this separation. His next business is to give a particular description of each of these natural divisions, beginning with the most essential fact, its elevation above the sea. If it is a valley, he notices its elevation at its origin and its termination, observing where its descent is regular and gradual, and where it declines with greater rapidity. If it is a plain, he notices at least its mean elevation, and observes in what cases it extends in a flat level, and in what cases it has an undulating surface; also if a smaller or larger portion of it is covered with swamps. This description of the surface is followed by that of the water-courses or drainage. After determining the sources of a stream, and the direction and length of its course, he mentions the amount of depression of its bed below the general surface of the valley or of the plain; and when it drains a plain, if there are bottoms or river-valleys formed on the surface of the plain, he mentions also the general extent of these bottoms. The distance to which a river is navigable is the next object of inquiry: if there are any natural impediments to the navigation, and if any successful attempts have been made to remove them, these facts also require mention. The extent of surface drained by each river, or by all the streams which ultimately unite in one channel; in other words, the extent of each river-basin, must also be ascertained. Next follows the climate. Here two points especially are to be attended to: the temperature of the air and the quantity of rain which falls, and of moisture in the atmosphere. As for the temperature of the air, not only the mean annual temperature is to be given or ascertained, but also that of the different seasons, and the regularity or irregularity of its changes, as such changes generally affect the health of the inhabitants in a sensible degree. As to moisture or rain, not only the annual quantity that falls should be noticed, but also its distribution at the different seasons. The character and the duration of the seasons must also be observed, and the prevalent winds; and especially the effect of the seasons on the progress of vegetation. It is necessary to know all these facts before a just notion can be formed of the fitness of any given tract of country for providing a population with food. And this capability of a country for the production of food,—or, in other words, its capabilities for agricultural purposes, is one of the most useful branches of geographical inquiry. The nature of the soil, and its fitness for different productions adapted to the climate of the tract, are therefore matters of primary importance in a geographical description. It is here proper to enumerate those objects of agriculture which are raised for food and as materials for clothing, and the proportion between the labour which they require and the value of the produce; and, in the next place, such productions as could be raised with ease and advantage, but which are not cultivated to any extent. Those objects which form articles of export, and enter into the market of the world, also claim a notice; and also such indigenous plants as are either of some use in the domestic economy of the inhabitants, or furnish a commodity for foreign trade. It is not the business of the geographer to enumerate all the particulars which constitute the botany or zoology of a district, for that would enlarge his science beyond all bounds and encroach upon the limits of others: the principle that must guide him in determining how much and what he must include in his geographical description of the botany and zoology of a country, will always be indicated by the question, Does the thing or object inquired after materially influence the capability of the country as a place fitted for the residence of man? Besides the useful domestic animals, it is only necessary to mention such wild ones as are useful to the inhabitants, either by providing them with food and clothing, or by supplying an article of commerce; and these animals only need be mentioned when they are found in great numbers. As for the mineral wealth of a country, the notice of that will be limited to those substances which are worked for the use of the inhabitants or for exportation.

In this way we conceive the geographer ought to describe in detail each natural division of a country; and when he has described two such tracts which are contiguous to one another, he must point out the boundary-lines by which nature has separated them, and the obstacles which she has placed to their mutual intercourse. If he finds that such boundary-lines are formed by mountain ranges, he has to notice their mean elevation, and likewise that of the mountain-passes by which the dividing range is crossed. He must also add what natural productions of the range contribute to the sustenance or comfort of the inhabitants of the adjacent tracts. When the range has numerous offsets and extensive valleys, and consequently occupies a considerable part of the country, he must treat it as a separate natural division, and describe it in detail like any other natural division.

When the geographer has described every natural division of a country in this way, and incorporated in his description the best attainable information on all the above-mentioned points, we think that he has done his duty, and may consider his labour as terminated. But our geographical treatises still contain other matter, which is not comprehended within the above enumeration of objects belonging to the science of geography. This extraneous matter is taken either from statistics, or from what is popularly called natural philosophy or from history; and it ought to be considered how far it is expedient to admit such matters into geographical treatises.

The knowledge of a country would properly be considered as incomplete without a general notion of the most important commercial and manufacturing towns within it. Such towns must therefore be mentioned, and at the same time it should be stated how far they facilitate the internal and external intercourse of a country. The political divisions of the country may be added or omitted; when added, they should be mentioned briefly, and in a very general way. Good maps supply any deficiency in geographical works in this respect.

We do not venture to exclude entirely from geographical works all mention of natural phenomena peculiar to a country. Some of these, as volcanoes and earthquakes, though they do not exercise a permanent influence on the welfare of the inhabitants, are frequently destructive of property or life, or of both. For that reason they ought to be noticed. Such phenomena as warm or mineral springs seem also to claim a notice, especially if distinguished by peculiar characters, as the Geysers in Iceland.

It is more difficult to determine how far it is proper to describe the remains of antiquity in geographical works. When the ruins of a great city still exhibit remarkable traces of its ancient grandeur, they certainly cannot be altogether excluded. But the true solution of these and other difficulties of the kind that may be suggested as to the matter admissible into a geographical treatise, seems to be this: these subjects are *specialties*, and if they belong to geography at all, do not belong to it as necessary component parts of it, but stand to it in such a relation as to admit of being introduced or omitted according to the taste and judgment of the writer, who in this, as in all branches of knowledge whose boundaries are incapable of precise determination, will show his good sense and his clear comprehension of his subject as much by what he omits as by what he takes in.

The political institutions of a country belong to its history, and not to its geography, and ought certainly to be excluded from geographical treatises, though they form a necessary part of most statistical and of all historical works. In the Admiralty 'Manual of Scientific Inquiry,' third edition (London, 1859), will be found the views which are suggested by the recent rapid progress of geographical science, on the principal points to which, in respect of geographical investigations, the attention of travellers should be mainly directed, embodied in an article by Mr. W. J. Hamilton, F.R.S., some time President of the Royal Geographical Society of London.

The local subjects of Descriptive Geography constitute in their alphabetical arrangement the GEOGRAPHICAL DIVISION of the ENGLISH CYCLOPÆDIA. The subjects of Physical Geography, considered as objects of science, such as DESERTS, FORESTS, MOUNTAINS, RIVERS, &c. will be found in their proper alphabetical places in the present division; and those belonging to the Geographical Distribution of organised beings have been given under their appropriate heads in the NATURAL HISTORY DIVISION. [ASTRONOMY; CHART; CLIMATE; GEODESY.]

GEOMETER, a person who is skilled in geometry; but the term had its meaning settled at the time when geometry was by very much the most important branch of mathematics: and now it generally means mathematician. For instance, the French (who make considerable use of the term) call Laplace *un géomètre*, though his writings are exclusively algebraical. The term must then be understood to signify simply mathematician.

GEOMETRICAL. Of this term, as opposed to algebraical or arithmetical, nothing need be said; but the peculiar conventions of geometry oppose it most frequently to the term *mechanical*. Every construction which can be made by the ruler and compasses, that is, which demands no points except such as can be found by the intersections of straight lines and circles, is *geometrical*: every construction which requires any other curve, or which tacitly requires such a motion of a straight line or circle as would generate any other curve, is *mechanical*. The reason is that it pleased the Greeks to use these terms as distinctive of the things which can and cannot be done by the straight line and circle only: a real and important distinction with an unfortunate name. For though names, when clearly understood, are of little consequence, yet this convention of geometry has caused many to waste their time and misapply their talents. A man, for instance, not well versed in mathematics, hearing that a *geometrical* quadrature of the circle has long been sought, and never been found, sets his invention to work, easily discovers a (mechanical) method of proceeding, and imagines that everything is geometrical which employs lines, solids, &c. in space.

The conic sections were not considered by the Greeks as geometrical instruments. Several writers speak as though the contrary had been the case; but it is certain that the solution by Menechmus of the problem of two mean proportionals, which employs the parabola, was not considered by Eutocius (who records it) as more geometrical than the others which he gives.

GEOMETRICAL PROGRESSION, PROPORTION, &c. [PROGRESSION, PROPORTION, &c.]

GEOMETRY (*γεωμετρία, geométria*, or land-measurement), the science which investigates the relations existing between parts of space, whether linear, superficial, or solid. But at the same time, the most common meaning of the word implies that the investigation is to take place under restrictions as to the instruments which may be employed. Of this we shall see more when we come to the geometry of the Greeks; in the meanwhile, geometry may be generally defined as the science of space. The closeness of the connection between *geometry*, and *Euclid* its founder, has made the two names almost identical. Although therefore, a part of the present article has been given in the BIOG. DIV. under the name of EUCLID, it is repeated here with some additions. As geometry is in all probability the most ancient subject to which actual demonstration was applied, we may thus account for the permanent association which has always existed between the idea of this science and that of rigorous deduction. To reason geometrically is a synonyme for to reason strictly: but abandoning this particular view of geometry, we shall devote the present article principally to such an imperfect sketch of the early progress of the science as its meagre history, combined with the narrowness of our limits, will allow.

There is a *stock history* of the rise of geometry, supported by the names of Strabo, Diodorus, and Proclus, namely, that the Egyptians, having their landmarks yearly destroyed by the rising of the Nile, were obliged to invent an art of land-surveying in order to preserve the memory of the bounds of property; out of which art geometry arose. This story, combined with another attributing the science directly to the gods, forms the first light which we have on the subject, and both in one are worthily sung by the poet who figures at the head of an obsolete English course of mathematics:—

"To teach weak mortals property to scan,
Down came geometry and formed a plan."

There is no proof whatever that the Egyptians were more of geometers than of astronomers [Astronomy], and the supposition that the rise of the Nile obliged the builders of the pyramids to make new landmarks once a year, requires at least contemporary evidence to make it history. At the same time, the question of the actual origin of geometry is a very difficult one, and any conclusion can only be of very moderate probability.

Among the Chinese, the Jesuit missionaries found very little knowledge of the properties of space; a few rules for mensuration, and the famous property of the right-angled triangle being all that they could ascertain. Of all the books which Gaubil could find professing to be written before B.C. 206, there is only one which contains anything immediately connected with geometry. From this writing (called Tcheou-pey) it is not very certain whether the Chinese possessed the property of the right-angled triangle generally, or only one particular case; namely, when the sides are 3, 4, and 5: and nothing appears which directly or indirectly resembles demonstration. The Hindoos produce a much larger body of knowledge, but of uncertain date. The works of Brahmegupta and Bhascara, of the 7th and 12th centuries after the Christian era (according to Colebrooke), contain a system of arithmetical mensuration which is certainly older than the compilers mentioned, and in which the property of the right-angled triangle is made to produce a considerable number of results; for instance, the method of finding the area of a triangle of which the three sides are given. By a figure drawn on the margin of some manuscripts, it appears that a demonstration of the property in question had been obtained. [Hypothenuse.] The circumference of the circle is given as bearing to the diameter the proportion of 3927 to 1250 by the latter writer; being exactly that of 3.1416 to 1. Brahmegupta takes the proportion of the square root of 10 to 1, or 3·16 to 1. The superior correctness of the later writer could not have arisen from any intermediate communication with Europe, since the true ratio was not known so near as 3·1416 till after the 12th century; and the Persians (as appears by the work of Mohammed ben Musa) had adopted this ratio from the Hindoos, before the discovery of an equally exact ratio in Europe. This subject is noticed more in detail in the article Viga Ganita in the Biog. Div.; here we merely observe that though no date can be fixed to the commencement of geometry in India, yet the certainty which we now have that algebra and the decimal arithmetic came from that quarter, the recorded visits of the earlier Greek philosophers to Hindostan (though we allow weight rather to the tendency to suppose that philosophers visited India, than to the strength of the evidence that they actually did so), together with the very striking proofs of originality which abound in the writings of that country, make it essential to consider the claim of the Hindoos, or of their predecessors, to the invention of geometry. That is, waiving the question whether they were Hindoos who invented decimal arithmetic and algebra, we advance that the people which first taught those branches of science is very likely to have been the first which taught geometry; and again, seeing that we certainly obtained the former two either from or at least through India, we think it highly probable that the earliest European geometry also came either from or through the same country.

Of the Babylonian and of the Egyptian geometry we have no remains whatever, though each nation has been often said to have invented the science. In reference to the authorities mentioned above in favour of the Egyptians, to whom we may add Diogenes Laertius, &c., we may say that no one of the writers who tells the story in question is known as a geometer except Proclus, the latest of them all; and as if to give the assertion the character of an hypothesis, this last writer also adds that the Phenicians, on account of the wants of their commerce, became the inventors of arithmetic. In the Jewish writings there is no trace of any knowledge of geometry. So that allowing the Greeks to have received the merest rudiments either from Egypt or India, or any other country, it is impossible to name any quarter from which we can with a shadow of probability imagine them to have received a deductive system, to ever so small an extent. That their geometry, or any of it, came *direct* from India, is a supposition of some difficulty: those who brought it could hardly have failed to bring with it the decimal notation of arithmetic. That Pythagoras travelled into India, is (according to Stanley) only the assertion of Apuleius and Clemens Alexandrinus, though rendered probable by several of his tenets: the better authorities carry him no farther than Egypt.

Thales (600 B.C.) and Pythagoras (540 B.C.) founded the earliest schools of geometry. The latter is said to have sacrificed a hecatomb when he discovered the property of the hypothenuse before alluded to, and this silly story is repeated whenever the early history of geometry is given. A large collection of miscellanies might easily be made from the works of writers who were not themselves acquainted with geometry; but, rejecting such authorities, we shall content ourselves with citing Pappus and Proclus, both geometers, who, living in the fourth and fifth centuries after Christ, had abundant opportunities of hearing the stories to which we allude, and of receiving or rejecting them.

According to Proclus (book ii. ch. 4, Comm. in Eucl.) Pythagoras was the first who gave geometry the form of a science, after whom came Anaxagoras, Œnopides, Hippocrates of Chios (who invented the well known quadrature of the lunules), and Theodorus of Cyrene. Plato was the next great advancer of the science, with whom were contemporary Leodamas, Archytas, and Theætetus, of Thasus, Tarentum, and Athens. After Laodamas came Neoclides, whose disciple Leo made many discoveries, added to the accuracy of the elements, and gave a method of deciding upon the possibility or impossibility of a problem. After Leo came Eudoxus, the friend of Plato, who generalised various results which came from the school of the latter. Amyclas, another friend of Plato, and the brothers Menæchmus and Dinostratus made geometry more perfect. Theudius wrote excellent elements, and generalised various theorems. Cyzicinus of Athens cultivated other parts of mathematics, but particularly geometry. Hermotimus enlarged the results of Eudoxus and Theætetus, and wrote on *loci*. Next is mentioned Philippus, and after him Euclid, 'who was not much younger than those mentioned, and who put together elements, and arranged many things of Eudoxus, and gave unanswerable demonstrations of many things which had been loosely demonstrated before him.' He lived under the first Ptolemy, by whom he was asked for an easy method of learning geometry, to which he made the celebrated answer that there was no royal road. He was younger than the time of Plato, and older than Eratosthenes and Archimedes. He was of the Platonic sect.

Such is, very nearly entire, the account which Proclus gives of the rise of geometry in Greece.

Before the time of Euclid demonstration had been introduced, about the time, perhaps by the instrumentality, of Pythagoras; pure geometry had been restricted to the right line and circle, but by whom is not at all known; the geometrical analysis, and the study of the conic sections, as also the consideration of the problems of the duplication of the cube, the finding of two mean proportionals, and the trisection of the angle, had been cultivated by the school of Plato; the quadrature of a certain circular space had been attained, and the general problem suggested and attempted by Hippocrates and others; a curve of double curvature had been imagined and used by Archytas; writings existed both on the elements, and on conic sections, loci, and detached subjects. The little that is known of the biography of Euclid of Alexandria, will be found in the Biog. Div.

Besides the Elements, Euclid wrote, or is supposed to have written, the following works:—

1. *Σύγγραμμα Ψευδαρίων*, a treatise on Fallacies, preparatory to geometrical reasoning. This book, mentioned by Proclus, does not now exist, and there is no Greek work of which we so much regret the loss. Had it survived, mathematical students would not have been thrown directly upon the Elements, without any previous exercise in reasoning. [Mathematics.]

2. Four books of Conic Sections, afterwards amplified and appropriated by Apollonius, who added four others. So says Pappus. That Euclid did not write *any* books on conic sections—that he wrote these of Apollonius is wholly incredible—appears to us more than probable from the silence of Proclus the Platonist, who, eulogising Euclid the Platonist, and stating that he wrote on the regular solids (a part of geometry cultivated by the Platonists), being led thereto by Platonism, never mentions his writing on the still more Platonic subject of the conic sections. But that Aristæus had written on the subject is known, and that Euclid taught it cannot be doubted, any more than that Apollonius, like other writers, prefixed to his own discoveries all that he judged fit out of what was previously known on the subject.

3. *Περὶ Διαιρέσεων*, on Divisions. This work is mentioned by Proclus in two words. John Dee imagined the book of Mohammed of Bagdad (which is annexed to the English edition of Euclid hereinafter cited) on the divisions of surfaces to be that of Euclid now under consideration; but there seems to be no ground for this notion. The Latin of this work (from the Arabic) is given at the end of Gregory's Euclid, together with a fragment 'De Levi et Ponderoso,' attributed, without any foundation, to Euclid.

4. *Περὶ πορισμάτων*, on Porisms, in three books. This is mentioned both by Pappus and Proclus, the former of whom gives the enunciations of various propositions in it, but the text is so corrupt that they can hardly be understood. On this singular question, see the article Porism.

5. *Τόπων πρὸς ἐπιφάνειαν*, Locorum ad Superficiem: which we cannot translate. It is mentioned by Pappus, but has not come down to us.

The preceding works are either lost or doubtful; those which follow all exist, and are contained in Gregory's edition, in the order inverse to that in which they are here mentioned.

6. *Ὀπτικὰ καὶ κατοπτρικά*, on Optics and Catoptrics. These books are attributed to Euclid by Proclus, and by Marinus in the preface to the Data; or rather books on these subjects. Savile, Gregory, and others doubt that the books which have come down to us are those of Euclid, and Gregory gives his reasons in the preface, which are—that Pappus, though he demonstrates propositions in optics and also in astronomy, and mentions the Phænomena of Euclid with reference to the latter, does not mention the Optics with reference to the former—and that there are many errors in the works in question, such as it is not likely Euclid would have made. Proceeding on the supposition that rays of light are carried *from the eye to the object*, the first of these books demonstrates some relations of apparent magnitude, and shows

how to measure an unknown height by the well-known law of reflected light. In the second an imperfect theory of convex and concave mirrors is given.

7. *Φαινόμενα*, on Astronomical Appearances, mentioned by Pappus, and Philoponus (cited by Gregory). It contains a geometrical doctrine of the sphere, and though probably much corrupted by time, is undoubtedly Euclid's.

8. *Κατατομὴ κανόνος* and *εἰσαγωγὴ ἁρμονικὴ*, the Division of the Scale and Introduction to Harmony. Proclus mentions that Euclid wrote on harmony, but the first of these treatises is a distinct geometrical refutation of the principles laid down in the second, which renders it unlikely that Euclid should have written both. The second treatise is Aristoxenian, while the first proceeds on principles of which Gregory states he never found a vestige in any other writer who was reputed anterior to Ptolemy (to whom he attributes it). The second treatise is not geometrical, but is purely a description of the system mentioned, and as this treatise is not alluded to by Ptolemy nor by any previous writer on the subject, it is very probable that Euclid did not write it.

9. *Δεδομένα*, a book of Data. This is the most valuable specimen which we have left of the rudiments of the geometrical analysis of the Greeks. Before a result can be found, it should be known whether the given hypotheses are sufficient to determine it. The application of algebra settles both points; that is, ascertains whether one or more definite results can be determined, and determines them. But in geometry it is possible to propose a question which is really indeterminate, and in a determinate form, while at the same time the methods of geometry which give one answer may not give the means of ascertaining whether the answer thus obtained is the only one. Thus the two following questions seem equally to require one specific answer, to one not versed in geometry:—

Given, the area of a parallelogram, and the ratio of its sides; required, the lengths of those sides: and

Given, the area of a parallelogram, the ratio of its sides and one of its angles; required, the lengths of the sides.

The first question admits of an infinite number of answers, and the second of only one; or in the language of Euclid, if the area, ratio of sides, and an angle of a parallelogram be given, the sides themselves are given. The same process by which it may be shown that they are given serves to find them; so that the Data of Euclid may be looked upon as a collection of geometrical problems, in which the attention of the reader is directed more to the question of the sufficiency of the hypothesis to produce one result, and one only, than to the method of obtaining the result.

A preface to this book was written by one Marinus, the disciple and successor of Proclus, explaining at tedious length the distinction of "given" and "not given."

10. *Στοιχεῖα*, the Elements (of Geometry). For a long time writers hardly considered it necessary to state whose elements they referred to, since a certain book of the elements always signified that book of Euclid: and it was customary in England to call each book *an* element; thus in Billingsley's old translation the sixth book is called *the sixth element.*

The reason why the Elements have maintained their ground is not their extreme precision in the statement of what they demand [Axiom]; for it frequently happens that a result is appealed to as self-evident, which is not to be found in the expressed axioms. Neither does their fame arise from their never assuming what might be proved; for in the very definitions we find it asserted that the diameter of a circle bisects the figure, which might be readily proved from the axioms. Neither is it the complete freedom from redundancy, nor the perfection of the arrangement; for book i. prop. 6, which is very much out of place, considering that it is never wanted in the first book, is, in point of fact, proved again (though not expressed) in prop. 19. Neither is it the manner in which our ideas of magnitude are rendered complete, as well as definite: for instance, book iii. prop. 20, is incomplete with Euclid's definition and use of the term angle; nor with that term as used by him can the 21st proposition of that book be fully demonstrated without the help of the subsequent 22nd. In fact, the Elements abound in defects, which, if we may so speak, are clearly seen by the light of their excellencies: the high standard of accuracy which they inculcate in general, the positive and explicit statement which they make upon all real and important assumptions, the natural character of the arrangement, the complete and perfect absence of false conclusion or fallacious reasoning, and the judicious choice of the demonstrations, considered with reference to the wants of the beginner, are the causes of the universal celebrity which this book has enjoyed. We shall, in the article Mathematics, give our reasons for advocating the continuance of Euclid as a book of instruction, and shall now describe the contents of the Elements.

There are thirteen books certainly written by Euclid, and two more (the fourteenth and fifteenth) which are supposed to have been added by Hypsicles of Alexandria, of whom we do not doubt that he lived in the sixth century, though he is commonly placed in the second.

Book i. lays down the definitions and postulates required in the establishment of plane geometry, a few definitions being prefixed also to ii., iii., iv., and vi. It then treats of such properties of straight lines and triangles as do not require any particular consideration of the properties of the circle nor of proportion. It contains the celebrated proposition of Pythagoras.

From this book it appears that Euclid lays down, as all the instrumental aid permitted in geometry, the description of a right line of indefinite length, the indefinite continuation of such a right line, and the description of a circle with a given centre, the circumference of which is to pass through a given point. It is usual to say, then, that the ruler and compasses are the instruments of Euclid's geometry, which is not altogether correct, unless it be remembered that with neither ruler nor compasses is a straight line allowed to be transferred, of a given length, from one part of space to another. It is a plain ruler, whose ends are not allowed to be touched, and compasses which close the moment they are taken off the paper, of which the Greek geometry permits the use. It is altogether uncertain by whom these restrictive postulates were introduced, but it must have been before the time of Plato, who was contemporary with (if he did not come after) the introduction of those problems whose difficulty depends upon the restrictions. We may here observe that in actual construction the ruler might have been dispensed with. It was reserved for an Italian abbé, at the end of the 18th century, when all who studied geometry had, for two thousand years, admired the smallness of the bases on which its conclusions are built, to inquire whether, small as they were, less would not have been sufficient. In Mascheroni's 'Geometria del Compassa,' published at Pavia in 1797, it is shown that all the fundamental constructions of geometry can be made without the necessity of determining any point by the intersections of straight lines; that is, by using only those of circles. This singular and very original work was translated into French, and published at Paris in 1798 and 1828. It may be added that Benedetti, in the 16th century, and others after him, had shown that, granting the straight line, *only one circle* is absolutely necessary: that is, only one opening of the compasses.

On subjects particularly connected with the first book, see Axiom, Postulate, Parallels, Hypothenuse.

Book ii. treats of the squares and rectangles described upon the parts into which a line is divided. It opens the way for the application of geometry to arithmetic, and ends by showing how to make a square equal to any rectilinear figure. It also points out what modification the proposition of Pythagoras undergoes in the case of a triangle not right-angled. [Rectangle.]

Book iii. treats of the circle, establishing such properties as can be deduced by means of the preceding books.

Book iv. treats of such regular figures as can readily be described by means of the circle only, including the pentagon, hexagon, and quindecagon. It is of no use in what immediately follows.

Book v. treats of proportion generally, that is, with regard to magnitude in general. Whether this most admirable theory, which though abstruse is indispensable, was the work of Euclid himself, or a predecessor, cannot now be known. The introduction of any definitely numerical definition of proportion is rendered inaccurate by the necessity of reasoning on quantities between which no exact numerical ratio exists; for which see Incommensurables. The method of Euclid avoids the error altogether, by laying down a definition which applies equally to commensurables and incommensurables, so that it is not even necessary to mention this distinction. In the article Proportion we shall endeavour to show that this method is more simple than is generally supposed, and also that all substitutes for it have failed in rigorous deduction.

Book vi. applies the theory of proportion to geometry, and treats of similar figures, that is, of figures which differ only in size, and not in form.

Book vii. lays down arithmetical definitions; shows how to find the greatest common measure and least common multiple of any two numbers; proves that numbers which are the least in any ratio are prime to one another, &c.

Book viii. treats of continued and mean proportionals, showing when it is possible to insert two integer mean proportionals between two integers.

Book ix. treats of square and cube numbers, as also of *plane* and *solid* numbers (meaning numbers of two and three factors). It also continues the consideration of continued proportionals, and of prime numbers, shows that there is an infinite number of prime numbers, and demonstrates the method of finding what are called *perfect* numbers.

Book x. contains 117 propositions, and is entirely filled with the investigation and classification of certain incommensurable quantities. It shows how far geometry can proceed in this branch of the subject without algebra; and though of all the other books it may be said that they remain at this time as much adapted for instruction as when they were written, yet of this particular book it must be asserted that it should never be read except by a student versed in algebra, and then not as a part of mathematics, but of the history of mathematics. In the article Irrational Quantities we shall translate the phrases of Euclid into algebraical language, by means of which we have no doubt that many students will be enabled to read the book of Euclid with profit. The book finishes with a demonstration that the side and diagonal of a square are incommensurable. From this book it is most evident that the arithmetical character of geometrical magnitude had been very extensively considered; and it seems to us sufficiently clear that an arithmetic of a character approximating closely to algebra must have been the guide, as well as that some definite object was sought—perhaps the attainment of the quadrature of the circle.

Book xi. lays down the definitions of solid geometry, or of geometry which considers lines in different planes and solid figures. It then proceeds to treat of the intersections of planes, and of the properties of parallelopipeds, or what might be called solid rectangles or right solids.

Book xii. treats of prisms, cylinders, pyramids, and cones, establishing the properties which are analogous to those of triangles, &c., in the first and sixth books. It also shows that circles are to one another as the squares on their diameters, and spheres as the cubes on their diameters, in which, for the first time in Euclid, the celebrated method of EXHAUSTIONS is employed, which, with the theory of proportion, forms the most remarkable part of this most remarkable work. In the article just cited we have referred to the present one for some account of this method, which we now give.

The only method of reasoning upon the length, area, or solidity, of curve lines or surfaces, is by observing the properties of inscribed polygons or polyhedrons, which may, by sufficiently increasing the number of their sides or faces, be made to approach as near as we please to continuous curvilinearity. But since the rigour of geometry is not content with proving that a proposition may be considered as nearly true as we please, and will not infer that one line is equal to another because it can be shown that their difference is (no matter how) small; Euclid (or some of his predecessors, but most probably Euclid, if we may judge by the character of his discoveries given by Proclus) invented this method of exhaustions, which may be considered as contained in the following two propositions.

I. If from A more than its half be taken, and from the remainder more than its half, and so on, the remainder will at last become less than B, where B is any magnitude named at the outset (and of the same kind as A), however small. This proposition may be easily proved, and is equally true if the fixed proportion abstracted each time be half or less than half.

II. Let there be two magnitudes, P and Q, both of the same kind; and let a succession of other magnitudes, called X_1, X_2, X_3 . . . be each nearer and nearer to P, so that any one, X_n, shall differ from P less than half as much as its predecessor differed. Let Y_1, Y_2, Y_3 . . . be a succession of quantities similarly related to Q; and let the ratios of X_1 to Y_1, of X_2 to Y_2, and so on, be all the same with each other, and the same with that of A to B. Then it must be that P is to Q as A to B. (It is obvious, from the conditions, that if X_1 be greater than P, Y_1 is greater than Q, &c., &c.) Suppose X_1, X_2, &c., less than P, and therefore Y_1, Y_2, &c., less than Q. Then, if A be not to B as P to Q, A is to B as P to some other quantity S greater or less than Q: say less than Q. Then (by hypothesis and I.), we can find some one of the series Y_1, Y_2 . . . (say Y_n) which is nearer to Q than S is to Q; and which is therefore greater than S. Then, since X_n is to Y_n as A to B, or as P to S, we have X_n is to Y_n as P to S, or X_n to P as Y_n to S: from which, since X_n is less than P, Y_n is less than S. But Y_n is also greater than S, which is absurd; therefore A is not to B as P to less than Q. Neither is A to B as P to more than Q (which call S), for in that case S is to P as B to A: let S be to P as Q to T, then S is to Q as P to T; from which, S being greater than Q, P is greater than T. But B is to A as S to P, that is, as Q to less than P, which is proved to be impossible by the reasoning of the last case. Consequently, A is not to B as P to more than Q, or to less than Q; that is, A is to B as P to Q. Which was to be shown. Let P and Q be two circles, A and B the squares on their diameters, X_1 and Y_1 inscribed squares, X_2 and Y_2 inscribed regular octagons, X_3 and Y_3 inscribed regular figures of sixteen sides, &c.: the preceding process gives the proof that circles are to one another as the squares on their diameters.

Book xiii., the last of those written by Euclid, applies some results of the tenth book to the sides of regular figures, and shows how to describe the five regular bodies. [SOLIDS, REGULAR.]

Books xiv. and xv., attributed to Hypsicles of Alexandria, treat entirely of the relative proportions of the five regular solids, and of their inscription in one another.

The writings of Euclid continued to be the geometrical standard as long as the Greek language was cultivated. The Romans never made any progress in mathematical learning. Boethius [BOETHIUS, in BIOG. DIV.] translated, it is said, the first book of Euclid (Cassiodorus, cited by Heilbronner); but all which has come down to us on the subject from this writer (who lived at the beginning of the 6th century) is contained in two books, the first of which has the enunciations and figures of the principal propositions of the first four books of the Elements, and the second of which is arithmetical. Some of the manuscripts of this writer contain an appendix which professes to give an account of a letter of Julius Cæsar, in which he expresses his intention of cultivating geometry throughout the Roman dominions. But no such result ever arrived so long as the Western Empire lasted; and this short account of Roman geometry is a larger proportion of the present article than the importance of the subject warrants. These books of Boethius continued to be the standard text-books until Euclid was brought in again from the Arabs.

Among the last-mentioned race geometry made no actual progress, though many of the works of the Greek writers were translated, and Euclid among the rest. There are several Arabic versions, the most perfect of which is that of Othman of Damascus, who augmented the usual imperfect translations by means of a Greek manuscript which he saw at Rome. D'Herbelot (at the words Aklides and Oclides) states that the Orientals believe Euclid to have been a native of Tyre, and also that they frequently gave his name to the science which he taught. The same author gives the name of the Arabic versions, one of which, that of Nasir-eddin, the most celebrated of all, was printed at the Medicean press at Rome in 1594. The astronomer Thabet ben Korrah [ASTRONOMY] was one of the translators, or rather, perhaps, revised the translation of Honein ben Ishak, who died A.D. 873. There is a manuscript in the Bodleian Library, purporting to be the translation of the latter edited by the former.

The first translation of Euclid into Latin, of which the date can be tolerably well fixed, is that of Athelard, or Adelard, a monk of Bath, who lived under Henry I. (about A.D. 1150). We have given [CAMPANUS, in BIOG. DIV.] a summary of authorities to show that Campanus, supposed to be another translator of Euclid, lived after this period; but we are inclined to believe that this translation (so called) of Campanus (printed A.D. 1482), is in fact that of Athelard, with a Commentary by Campanus. For Campanus is not expressly described in the book as a translator (see article cited), but as a commentator; add to which, that there is in the Bodleian Library a manuscript entitled 'Euclidis, &c.. ex versione Adelardi de Arabico, una cum commento Magistri Campani Novariensis.' Scheibel (cited by Camerer and Hauber, in the preface of their edition, presently noticed) states that in his copy of Campanus the fact of the translation being that of Adelard was noted in a handwriting apparently as old as the edition itself. The point might be settled by a comparison of the printed Campanus and the manuscript in the Bodleian. With regard to this version, it is stated (in the preface just cited) that it differs from the one of Nasir-eddin. With the precedent just cited, we may be allowed to state that in a copy of Campanus which we have examined, some ancient handwriting, completely obliterated, is attached to Ratdolt's preface. Chemical means have succeeded in recovering a few unconnected words only, among which are "ben Honein" and "Tebit ben Corra," expressing perhaps the opinion of the writer that the version chosen by Adelard or Campanus was that of the two Eastern editors who have been previously mentioned.

There is a considerable number of Greek manuscripts of the Elements, for which see Fabricius, Heilbronner, and the preface of Peyrard. There is no account of the manuscripts which they consulted by the earlier Latin translators (from the Greek), nor by Gregory. It appears however that several, if not many, of the manuscripts are entitled *Εὐκλειδου στοιχειων βιβλια ιε ἐκ των θεωνος συνουσιων*, from which it was inferred that the compilation of the elements was the work of Theon, from the materials left by Euclid. It is certain that Theon, in his commentary on the Almagest, speaks of his edition (*ἐκδοσις*) of Euclid, and mentions that the part of the last proposition which relates to the sectors was added by himself. On looking at that proposition, it is found that the demonstration relative to the sectors comes after the "*ὅπερ ἔδει δεῖξαι*," with which Euclid usually ends his propositions. And Alexander, the commentator on Aristotle, who lived before Theon, calls that the *fourth* proposition of the tenth book which is the *fifth* in all the manuscripts. We can then distinctly trace the hand of Theon as a commentator, and may suspect that he performed the duty of a revising editor to the work of Euclid as it now appears; but there is not the smallest reason to suppose that Theon actually digested the work into the form which it now has. These remarks relative to the claims of Theon were first made by Sir Henry Savile, who opened the chair of geometry which he founded at Oxford by thirteen lectures on the fundamental parts of the first book of Eucid, which were delivered in 1620, and published in 1621.

We now give a short summary of the early editions of Euclid, which have appeared in Greek or Latin. It is unnecessary to specify the common editions of Simson, Playfair, &c., &c., which confine themselves to the first six books, and the eleventh and twelfth, and are generally known.

I. Editions of the whole of Euclid's works. An imperfect Latin edition, by Bartholomew Zamberti, Venice, 1505. But the principal edition of all the works of Euclid is that published by the Oxford press in 1703, under the care of David Gregory, then Savilian professor.

II. Greek editions of the Elements only. (1.) An edition curâ Simonis Grynæi, Basel, 1533, with the commentary of Proclus. (2.) The Paris edition by Peyrard, 1814–18, in three volumes quarto, containing the Elements and Data, Greek and French. It is the first edition which has readings from various manuscripts. (3.) The Berlin edition, by August, 1826, 8vo., containing the thirteen books of the Elements, in Greek, with a selection of readings from Peyrard and from other manuscripts.

III. Latin editions of the Elements only. (1.) That of Campanus, the first Euclid printed, Ratdolt, Venice, 1482. (2.) A reprint of the preceding, marked 'Vincentiæ, anno salutis, 1491.' (3.) An edition containing the text and comment of Campanus, from the Arabic; also the text and comment of Zamberti, from the Greek; Paris, Henry Stephens, 1505; and again in 1516. This edition is very commodious for a general comparison of the Greek and Arabic. (4.) Edition of Lucas Pacioli, Venice, 1509. (5.) Edition of Henry Stephens, Paris, 1516. These five editions are in folio; the second and fourth are very scarce. The first edition of Clavius is that of Rome, 1574; of Commandine, Pesaro, 1572. [Clavius; Commandine, in Biog. Div.]

IV. Earliest editions of the Elements in modern tongues. *English*:—'The Elements of Geometry of the most ancient philosopher Euclid of Megara, &c.,' by H. Billingsley, with a preface by John Dee, London, 1570, and again in 1661. *French*:—'Les quinze livres des Eléments, &c., &c.,' Par D. Henrion, Mathematicum, first edition, Paris, 1565? second, 1623, with various others. According to Fabricius, there was an edition by Peter Forcadel, in 1565. *German*:—'Die sechs ersten bucher, &c.,' by William Holtzmann, Augsburg, 1562. Scheubelius had previously given the 7th, 8th, and 9th books, in 1555. *Italian*:—'Euclide Megarense Philosopho, &c.,' per Nicolo Tartalea, Venice, 1543. *Dutch*:—'De ses erste boecken Euclidis, &c.,' dor Jan Pieterszoon Dou, Amsterdam, 1608 (or 1606). *Swedish*:—'De sex forsta, &c.,' by Marten Stromer, Upsal, 1753. *Spanish*:—By Joseph Saragoza, Valentia, 1673. Murhard (compared with Fabricius) is the authority for all of these, except the first.

It has long ceased to be usual to read more of Euclid than the first six books and the eleventh. Those who wish to see more of the Elements will probably most easily obtain those of Williamson (London, 1788, two volumes 4to.), the translation of which is very literal. Those who prefer the Latin may find all the twelve books in the edition of Horsley (from Commandine and Gregory), Oxford, 1802. The number of editors of Euclid is extremely great, but our limits will not allow of further recapitulation.

The progress of geometry is connected with the names of Archimedes, Apollonius, Theon, &c., and it continued to flourish at Alexandria till the taking of that town by the Saracens, A.D. 640. But its latter day produced only commentators upon the writers of the former, or, at most, original writers of no great note. In the articles Locus, Porism, Duplication, Proportional, will be found some of the details of the Greek geometrical analysis. Spherical trigonometry, or rather that portion of their geometry which supplied its place in astronomy, is connected with the names of Hipparchus, Meuelaus, Theodosius, Ptolemy. The following list contains the names of the most celebrated geometers who lived before the decline of the Greek language: the dates represent nearly the middle of their lives, but are in many instances uncertain:—

Thales, B.C. 600; Ameristus? Pythagoras, 550; Anaxagoras; Œnopides; Hippocrates, 450; Theodorus; Archytas? preceptor of Plato; Leodamas; Theætetus; Aristæus, 350; Perseus? Plato, 310; Menæchmus, Dinostratus, Eudoxus, contemporaries of Plato: Neoclides; Leon; Amyclas; Theudius; Cyzicinus; Hermotimus; Philippus: Euclid, 285; Archimedes, 240; Apollonius, 240; Eratosthenes, 240; Nicomedes, 150; Hipparchus, 150; Hypsicles, 130? Geminus, 100; Theodosius, 100; Menelaus, A.D. 80; Ptolemy, 125; Pappus, 390; Serenus, 390; Diocles? Proclus, 440; Marinus? Isidorus? Eutocius, 540.

The age of Diophantus is not sufficiently well known even for so rough a summary as the preceding; he is usually given to the 2nd century, we place him at the end of the 6th century.

The following is the summary of books of geometrical analysis (qui ad resolutum locum pertinent), given by Pappus as extant in his time; of Euclid, the Data, three books of porisms, and two books *locorum ad superficiem*; of Apollonius, two books *de proportionis sectione*, two *de spatii sectione*, two *de tactionibus*, two *de inclinationibus*, two *planorum locorum*, and eight on conic sections; of Aristæus, five books *locorum solidorum*; of Erastosthenes, two books on finding mean proportionals. But besides these he describes a book (of Apollonius) which treats *de determinatâ sectione*.

The manifold beauties of the Elements of Euclid secured their universal reception, and it was not long before geometers began to extend their results. It became frequent to attempt the restitution of a lost book by the description given of it by Pappus or others; and from Vieta to Robert Simson, a long list of names might be collected of those who have endeavoured to repair the losses of time. On the advance of geometry in general, the reader may consult the lives of Vieta, Metius, Magini, Pitiscus, Snell, Napier, Guldinus, Cavalieri, Roberval, Fermat, Pascal, Descartes, Kepler, &c., &c., in the Biog. Div. and also the article Quadrature of the Circle.

The application of algebra to geometry, of which some instances had been given by Bombelli, and many more by Vieta, grew into a science in the hands of Descartes (1596–1650). It drew the attention of mathematicians completely away from the methods of the ancient geometry, and considering the latter as a method of discovery, the change was very much for the better. But the close and grasping character of the ancient reasoning did not accompany that of the new method: algebra was rather a half-understood art than a science, and all who valued strictness of demonstration adhered as close as possible to the ancient geometry. This was particularly the case in our own country, and unfortunately the usual attendants of rigour were mistaken for rigour itself, and *vice versâ*. The algebraical symbols and methods were by many reputed inaccurate, while the same processes, conducted on the same principles, in a geometrical form, were preferred and even advanced as more correct. Newton, an admirer of the Greek geometry, clothed his Principia in a dress which was meant to make it look (so far as mathematical methods were concerned) like the child of Archimedes, and not of Vieta or Descartes; but the end was not attained in reality, for though the reasoning is really unexceptionable, yet the method of exhaustions must be applied to most of the lemmas of the first section, before the Greek geometer would own them.

The methods of algebra, so far as expressions of the first and second degrees are concerned, apply with great facility to many large classes of questions connected with straight lines, circles, and other sections of the cone. Practical facility was gained by them, frequently at the expense of reasoning: the time came when a new Descartes showed how to return to geometrical construction with means superior to those of algebra, in many matters connected with practice. This was Monge, the inventor of *descriptive geometry*. The science of perspective and many other applications of geometry to the arts had previously required isolated methods of obtaining lines, angles, or areas, described under laws not readily admitting of the application of algebra, and its consequence, the construction of tables. The descriptive geometry is a systematised form of the method by which a ground-plan and an elevation are made to give the form and dimensions of a building. The projections of a point upon two planes at right angles to one another being given, the position of the point itself is given. From this it is possible, knowing the projections of any solid figure upon two such planes, to lay down on either of those planes a figure similar and equal to any plane section of the solid. In the case where the section is a curve it is constructed by laying down a large number of consecutive contiguous points. The methods by which such an object is to be attained were generalised and simplified by Monge, whose 'Géométrie Descriptive' (the second edition of which was published in 1820) is one of the most elegant and lucid elementary works in existence.

The methods of descriptive geometry recalled the attention of geometers to the properties of projections in general, of which such only had been particularly noticed as could be applied in the arts of design or in the investigation of primary properties of the conic sections. From the time of Monge to the present this subject has been cultivated with a vigour which has produced most remarkable results, and promises more. Pure geometry has made no advance since the time of the Greeks which gives greater help to its means of invention than that which the labours of what we must call the school of Monge have effected. One of the most distinguished pupils of this great master, M. Chasles, published an 'Apercu historique des méthodes en Géométrie,' forming the eleventh volume of the 'Mémoires Couronnés' of the Academy of Brussels, a work of great importance in the historical point of view.

On the history of geometry, as distinguished from other parts of mathematics, there is very little to cite. The references in the article Mathematics may be consulted.

GEOMETRY OF THE GREEKS. [Geometry.]

GEOPO'NIKA (or, a 'Treatise on Agriculture'), is the title of a compilation, in Greek, of precepts on rural economy, extracted from ancient writers. The compiler, in his proemium, shows that he was living at Constantinople, and dedicated his work to the Emperor Constantine, "a successor of Constantine, the first Christian emperor," stating that he wrote it in compliance with his desire, and praising him for his zeal for science and philosophy, and for his philanthropy. This emperor is supposed by some to have been Constantine Porphyrogenitus, and the compilation is generally ascribed to Cassianus Bassus, a native of Bithynia, who however is stated by others to have lived some centuries before the time of Porphyrogenitus. The question of the authorship of the 'Geoponika' has excited much discussion. Needham, in his Greek and Latin edition of the 'Geoponika,' Cambridge, 1704, has treated the subject at great length. The work is divided into twenty books, which are subdivided into short chapters, explaining the various processes of cultivation adapted to various soils and crops, and the rural labours suited to the different seasons of the year; with directions for the sowing of the various kinds of corn and pulse; for the training of the vine, and the art of wine-making, upon which the author is very diffuse. He also treats of olive plantations and oil-making, of orchards and fruit-trees, of evergreens, of kitchen-gardens, of the insects and reptiles that are injurious to plants, of the economy of the poultry-yard, of the horse, the ass, and the camel; of horned cattle, sheep, goats, pigs, &c., and the care they require; of the method of salting meat; and, lastly, of the various kinds of fishes. Every chapter is inscribed with the name of the author from whom it is taken, and the compiler gives at the beginning of the first book a list of his principal authorities, who are Africanus, Anatolius, Apuleius, Berytius, Damogeron, Democritus, Didymus, Dionysius Uticensis (the translator of Mago, the Carthaginian writer on agriculture), Diophanes, Florentinus, Leontius, Pamphilus, Paxamus, the Quintilii, Sotion, Varro, Vindanonius, and Zoroaster. Other authors besides these are quoted in the course of the work. Two or three chapters are inscribed with the name of Cassianus, who speaks of himself in them as a native of

Maratonymus in Bithynia, where he had an estate. ('Geoponika,' book v., ch. 6 and 36.) The work is curious, as giving a course of ancient agriculture collected from the best authorities then existing. The best edition of the 'Geoponika' is that of N. Niclas, in Greek and Latin, with notes and indexes, 4 vols. 8vo, Leipzig, 1781.

GEORGIUM SIDUS. [URANUS.]

GERMAN SILVER. As its name implies, this alloy was originally produced in Germany, and was obtained by smelting an ore found at Hilburghausen, near Suhl, in Henneberg. An alloy, however, very similar in appearance and properties has long been known to the Chinese under the name of *pakfong*, or white metal.

German silver is composed of the metals nickel, copper, and zinc, though in somewhat variable proportions. The following are examples of the amounts of the several metals contained in four specimens, each of different quality :—

	I.	II.	III.	IV.
Copper . . .	59·2	60	55·0	45·7
Nickel . . .	14·8	20	20·6	34·3
Zinc . . .	26·0	20	24·4	20·0
	100·0	100	100·0	100·0

No. 1 is perhaps the commonest made. No. 2 is much used. No. 3 is a very beautiful alloy, but little inferior in beauty to silver itself; it is sometimes called *electrum*. No. 4 is the richest in nickel that can be conveniently worked. For articles requiring much soldering, about 3 per cent. of lead is introduced; and where brittleness is not an objection, 2½ per cent. of iron may be added; the hardness and susceptibility of high polish being in the latter case greatly heightened. *Tutenag*, a kind of German silver used in casting operations, is composed of 45·7 of copper, 17·4 of nickel, and 36·9 of zinc.

In furnace operations with German silver a quantity of zinc is always volatilised and oxidised, and must be allowed for by at first adding a larger quantity of that metal than is required to form the alloy.

GESTURE. [ORATORY.]

GETÆ, the name of a northern tribe mentioned in Roman history, inhabiting the country on both banks of the Danube, near its estuary, and along the western shores of the Euxine. [DACIA, in GEOG. DIV.]

GHEE, a species of butter used by the natives of India, and prepared by boiling, so that it will keep for a considerable time; it is sometimes used when a year old. The milk, when first taken from the animal, is boiled in earthen pots for at least an hour, and frequently for two and even three hours; it is then allowed to cool, and a little curdled milk, called Dhye, is added to promote its coagulation. By the next morning the whole mass has been converted into dhye, or coagulated acid milk. About five or six inches in depth are then taken from the top of each pot and put into an earthen jar, where it is churned by turning round in it a split bamboo with a very quick motion. After half an hour's churning, some hot water is added, and the operation is continued for another half-hour, when the butter forms. When this butter has been kept two or three days, and has become rancid, as it will during that time in so hot a climate, it is melted in an earthen pot, and boiled until all the water that may be mixed with it is evaporated; a little dhye and salt, or betel-leaf, is then added, and it is put into pots to be kept for use. It has a strong smell, and, although very distasteful to Europeans, is in general consumption among all the natives who can afford to buy it. Ghee is a very important article of internal traffic through a great part of India.

GHIBELLINES. [GUELPHS.]

GIBBOUS, convex on both sides; a term particularly applied to the moon when more than half grown.

GIFT (Law), *donum*, *donatio*, is the transferring of the property in a thing by one man to another, voluntarily and without any valuable consideration.

The giver is called the donor, and he to whom the thing is given is called the donee. By the common law, real estate might pass as a gift by livery of seisin without deed; but by stat. 29 Charles II. c. 3, a deed or note in writing is rendered necessary to the transfer of real estate. To complete a gift of goods and chattels, not effected by writing, delivery is absolutely necessary; for until then the transaction is not properly a gift, but a contract, and the English law will not compel a man to perform his contract unless it is founded on good or valuable consideration.

Gifts are looked at with some degree of suspicion by the law of England, and are in some cases declared void, as against creditors and purchasers for a valuable consideration. [BANKRUPT.]

The distinctions laid down by the civil law as to gifts were numerous. It distinguished gifts into two classes, proper and improper: the proper gift being such as is recognised by the English law; the improper, gifts in consideration of marriage, and that species of gift termed *donatio mortis causâ*. According to the law of England, marriage is a valuable consideration, and consequently gifts upon that account are supported against purchasers and creditors.

Many curious distinctions relating to gifts exist in the Hindoo law. (See Colebrooke's 'Digest, Hindoo Law,' b. ii., c. 4.) As to the law regulating voluntary gifts established by the Code Napoleon, see 'Cod. Civ.,' b. 3, tit. 2.

GILDING. Although there are many varieties of gilding, the only kinds which need separate mention in this place are *Metal-gilding* and *Wood-gilding*. The reader will find an account of the modern process of *Electro-gilding*, under ELECTRO-METALLURGY; of *Fibre-gilding*, under GOLD LACE MANUFACTURE; of *China-gilding*, under PORCELAIN; and of *Book-gilding*, under BOOKBINDING.

Metal-gilding. The process of metal-gilding is one of the most delicate in the manufactures in metal; seeing that its success depends on a nicety of eye, a dexterity of hand, and a practical acquaintance with the chemical operations involved in it, which cannot be acquired without several months' or even years' experience. Mechanical errors and difficulties are in most cases detected and remedied with much greater facility than those which arise in the chemical branch of manufactures. To these latter the processes of gilding and colouring are particularly subject, and more especially that of gilding.

The gold made use of for the purpose of metal-gilding is called "fine gold," and is perfectly free from alloy. Its form is that which, in metals, is usually termed "shot," from its having been poured or shot when in a fluid state, into cold water. This operation divides it into pieces of various shapes and sizes, from the smallest grain, scarcely perceptible by the naked eye, to the dimensions of a pea or a nut. This form of the metal is best adapted for the gilder's purpose.

The union of the gold with the metal to be gilt is effected through the agency of mercury. The gold and mercury are first combined, by boiling the former in about five or six times its weight of the latter. These proportions are put into an iron ladle, which must have been previously lined with a coating of whiting and water, and then carefully and thoroughly dried. Should there be any moisture left in the lining, or if any cracks should expose the naked surface of the iron, the ebullition of the mercury is so rapid there, owing to the more rapid conduction of the heat, that a portion of the amalgam would be thrown out by the violence of the action. It is most economical to place the ladle and its contents within the heated iron cylinder used for the evaporation of the mercury from the articles when gilt, by which arrangement a considerable portion of the mercury which is evaporated during the process is retained by the condensers. The time necessary for dissolving all the gold in the mercury varies according to the hardness or softness of the gold (that which has been more *annealed* by the refiner appearing browner than the harder and yellower, and requiring a longer time for complete solution), and according to the larger or smaller size of the fragments of gold made use of. In general, half a troy pound of gold is completely dissolved by being kept at the boiling temperature of mercury for about twenty or twenty-five minutes. It is obvious that the boiling should be as gentle as possible, since fast boiling ensures no higher a temperature, and evaporates a greater quantity of quicksilver.

When it has been sufficiently boiled, the amalgam is poured out into cold water, by which it loses a great part of its fluidity, and becomes semi-fluid; the consistence depending, of course, on the quantity of quicksilver originally made use of, and the proportion of it that has been evaporated. The amalgam is then put into a piece of chamois skin, and squeezed; by which means the particles of quicksilver escape through the pores of the leather, while those of the gold are safely retained. When the mass is felt to be hard and unyielding within the leather, it is weighed, and its value is determined by considering five parts by weight of the amalgam as equal to one part by weight of the gold employed. The amalgam then, if good, is of about the consistence of a stiff clay, has a greasy and gritty feel on being divided by a bone spatula, and is in the most convenient state for being weighed out into the portions requisite for each respective quantity of work. If however the gold be adulterated or the mercury be impure, the amalgam often approaches more or less to fluidity, appears dirty, and deposits a black adhesive scum on every thing with which it comes in contact. The main object of bringing the amalgam to this consistence and these proportions is to have it in a form convenient for division and apportionment, as well as for the sake of having a uniform standard by which to ascertain the quantity and value of the gold employed. As, however, this consistence is not adapted for being applied to its intended purpose, without a greater or less dilution by being again boiled for a short time in mercury, many metal-gilders, especially those who provide their own gold, prefer to weigh out the gold which they intend to use, and then to mix it at once with the quantity of quicksilver which experience has taught them to be proper and necessary, and which varies according to the nature of the articles to be covered with it; for such articles as are wrought into deeply indented or highly ornamented patterns, or which are to have their surfaces completely covered, require a more fluid amalgam than those which have a smoother superficies, or which are to be only partially gilt.

On the application of this amalgam to the surfaces of copper, brazen, or mixed metal articles, it is found that, as there is no chemical affinity, and consequently no principle of mutual cohesion, between the substances thus brought into contact, the direct union of them is impossible. Nor can it be effected by allowing them to remain in contact for any length of time. The intervention of a solution of nitrate of mercury is therefore used. This salt is made by pouring a table-spoonful of quicksilver into about a quart of strong nitric acid, which is termed in commerce "gilders' aquafortis;" the red fumes of nitrous gas are instantly evolved, and the mercury is rapidly united with the acid, with the production of considerable heat. This solution is, by the unscientific operatives, termed "quick-water," the monosyllable "quick" being, in their language, a sufficient representative for the more tedious appellation of "quicksilver;" and the workshop name of this liquid has caused the appellation of *water-gilding* to be given to that which would more properly be called *metal-gilding*. When it is uncontaminated by the presence of any foreign substance, the "quick-water" is white and pellucid.

When a piece of copper or brass is immersed in or brought in contact with this solution, its surface is immediately converted into an amalgam. To this amalgamated surface mercury and gold amalgam closely adheres, by means of the molecular attraction of the particles of the fluid metals for each other.

The manner in which this agent is applied in practice varies according to the kind of articles about to be gilt. If they are small, strong, and to be gilt all over, as copper buttons, buckles, and rings, a quantity of them, which should not exceed three or four pounds in weight, is put into a deep glazed earthen pan or "jowl;" to these are added about three or four tea-spoonfuls of the "quick-water," together with the requisite portion of amalgam. The whole is then thoroughly stirred with a brush or stick, till the amalgam entirely covers the surface of every article, more particularly the indentations and sunken parts, which are the last to receive a coating, from their being less exposed to the contact of the fluids. When they are completely covered, they are by some gilders rinsed in cold water and dried by shaking in a bag of warm sawdust; while by others this part of the process is postponed to a later period of the operation, and they are put, in their wet state, with the generated nitrate of copper still hanging about them, into the gilding-cage. This cage is made in a cylindrical form, and is generally about 18 inches in length by 9 or 10 in diameter. It is formed of coarse iron-wire gauze, supported by an external framework of iron, and furnished with a solid iron door at one extremity, which generally forms a sector of one-third of the circular end. It is provided with an axle, which extends to a length of about 3 feet from the end at which the door is placed, and is there terminated by a winch, and to a distance of 5 or 6 inches in the opposite direction. The articles under process of gilding are placed in this cage, and the door of it securely fastened; it is then suspended by its axle on two supports in an iron cylinder, which somewhat resembles a gas retort, and which is in a similar manner fixed into brickwork over a furnace or stove. The cylinder being previously heated by a coal fire beneath it, to such a degree as to be red-hot over a large proportion of its inferior surface, the cage is introduced, and the doors of the cylinder closed. The heated air contained within the cylinder soon raises the temperature of the substances immersed in it; and as the cage is kept continually revolving by means of the winch, which projects through an aperture in the doors, they have all an equable share of heat, and allow of a nearly equal evaporation of the mercury from all their surfaces. The farther extremity of the cylinder communicates with a chamber, which is in general built of masonry and plastered over all the internal surfaces. The floor of this chamber is covered to a depth of about two feet with cold water, which on coming into contact with the mercurial vapours condenses a portion of them, and causes them to return to the liquid form. If this condenser, however, were made quite close, a great portion of the mercurial vapour would return through the cylinder into the apartment or gilding shop, and thus not only be wasted, but materially injure the health of the persons engaged in the work. A communication extending obliquely upwards, and made of one or more ranges of iron stove-piping, is therefore connected with a second smaller condenser on the story above, and this is again repeated a third or perhaps a fourth time. A current of heated air is thus continually ascending from the lowest condenser, and establishes a perpetual draught through the cylinder, thus preventing the deleterious mercurial vapour from mixing with the atmosphere of the shop in which the work is going forward; some of the vapour is, however, necessarily wasted by this precaution. The condensers are opened at intervals of several months, and the quicksilver taken out, washed, and dried; it is sometimes found necessary again to distil it, to free it from all impurities.

After the cage, with its contents, has been in the cylinder for a length of time varying, according to the temperature at which it has been kept, from five minutes to a quarter of an hour, the mercury will be found to have entirely evaporated from the gilt surfaces. If the articles have been previously washed and dried, they will appear of a clear yellow colour; and they may be allowed to remain in the cylinder, the cage revolving as before, until they are sufficiently heightened in tint. If they have not been so treated previously, they will appear of a dark, soiled, dirty colour, being covered with an incrustation of oxide of copper and of iron, and other impurities. To remove these, the goods are taken out of the cage; and after being allowed to cool for a few minutes, they are thrown, while still warm, into weak quick-water, that is, diluted nitrate of mercury. This converts the gold again into amalgam, owing to the precipitation of a portion of the mercury by the copper, which is taken up with avidity by the gold. They are then washed with clean water, dried in warm sawdust, and again committed to the cage and cylinder, which, by the evaporation of the mercury, give them a clean colour. They may then be heightened, which is done by continuing to revolve them at the same high temperature within the cylinder, occasionally shaking them together, that they may all have an equal share of the heat. The end intended to be effected is a partial oxidation of the surface of the gold, caused by means of the increased temperature of the metal goods after the mercury has evaporated, and which remains unaffected by nitric or sulphuric acids after the slight film of oxide of copper has been instantaneously removed by their action. This partial oxidation occasions a slight difference of colour, which is perceptible to an experienced eye, and confers on the gold a degree of that orange colour which is so generally admired in golden and gilt articles.

Buttons and articles of a similar description are often gilt only on their tops, or on some other portion of their surfaces; while the remainder is left uncovered with gold, and of the native colour of the metal of which they are manufactured. This is accomplished in the mode described under BUTTON MANUFACTURE.

Many descriptions of articles would be injured or destroyed by the method of gilding just now described. Such are all those which are of considerable dimensions in proportion to the thickness of the metal out of which they are made; as well as those whose individual weight and extent of surface would expose them to such attrition from the rotatory motion of the cage as would occasion the gold laid on to be entirely or partially rubbed off in the process of its application. Besides this, there is in thin and fragile articles an imminent danger of their being broken when they are amalgamated and rendered brittle throughout a great part of their substance by the necessary immersion in the quick-water. To obviate the inconveniences that might hence result, a different method is employed, so far as regards the mechanical part of it, though the chemical principles on which it depends are precisely the same. Articles of this description are most commonly gilt only on one side. There are two modes of preventing the amalgam from adhering to those parts of the surface that are intended to be left bare. One is to lacquer those parts, and after the spirit of wine is thoroughly evaporated, to immerse them in the quick-water, and afterwards apply the amalgam; the gummy surface left behind by the lacquer is entirely unaltered by its contact with the mercurial solution; but its exposure to the high temperature necessary in the subsequent parts of the process chars the gum, blackens it, and causes it to peel off. The other mode of applying the gold is to distribute the quick-water over the parts requiring it by a small brush or camel's hair pencil, and these then have the amalgam applied as before; if, as is sometimes the case, the goods are to be entirely covered, they are immersed at once in the quick-water. The goods thus prepared are laid with the gilt surfaces uppermost on an open iron pan, of a shape something like that of a frying-pan, which is held over a coke fire. The chimney is made wide at the bottom, and narrows rapidly as it proceeds upwards, so as to collect as much as possible of the mercurial vapour, for the recovery of which no effort has hitherto been made. A great proportion however necessarily escapes into the apartment, and renders this mode of gilding much more unhealthy than the use of the cylinder and cage. As the mercury gradually evaporates from their surfaces, their position is changed, when requisite, by means of a short pair of tongs; and when entirely free from it, the process of quick-watering is performed.

Where the cylinder is employed, it is usually swept out daily, before the fire has heated it in the morning. A portion of the gold amalgam is rubbed off by the attrition of the cage, and falls on the interior surface of the cylinder, whose heat melts it wholly or partially, and it becomes mixed with the oxide of iron that is constantly in course of production by the elevated temperature of the cylinder. This being carefully collected and refined, is found to yield an average of about 1-30th of the gold employed, to which dividend the richer sorts have contributed from their superabundance a greater proportionate quantity than the commoner qualities.

Gilt articles of all the better qualities are submitted to an after-process called colouring, for the purpose of conferring on them a deeper orange tint than is natural to the gold itself, or can be obtained by the process of heightening already mentioned. The principle of this additional operation is always the same, though the methods resorted to differ greatly from each other. One of the compositions employed for this purpose is formed of twenty-four parts of nitrate of potash, ten of sulphate of alumina, five of sulphate of iron, and five of sulphate of zinc, boiled together in water, thoroughly mixed, and cooled without being allowed to crystallise. This mixture is formed into a thin paste with water, which is spread over the surfaces of the articles by their being immersed in it; and when they are placed on a heated iron plate, the warm gold surfaces become oxidised. A mixture is sometimes made of bees' wax and yellow ochre, which being rubbed over the gilt surfaces and burnt off, occasions on a similar principle the same result. Goods that are to appear bright are scratched over before colouring with a brush made of fine brass wire.

Most gilt articles are burnished by a stone burnisher, formed of a polished piece of black hæmatite. This is fixed into a proper handle. Small articles, as buttons, &c., are placed in a lathe, and the stone applied to them as they revolve; those that do not admit of this are burnished by hand on a table or bench.

Besides copper and brass, several other substances admit of being gilt. Silver is gilt in a manner similar to that above described. Steel and iron are gilt by being immersed in a mixture of the nitro-muriate (or more properly the chloride) of gold with sulphuric ether or alcohol. By combining these liquids together, an alcoholic solution of gold is formed, from which the metal is precipitated by the iron or steel. Many applications of gilt metal are now superseded by the remarkable electrotype process in the way described in the article already adverted to.

Wood-Gilding. Wood work, whether plain or carved, is gilt by the following processes. Parchment-size is dissolved in water by heat, and a little whiting mixed with it. This composition is brushed over the picture-frame or other article to be gilt. The holes and cracks that may be in it are then filled up with a mixture of the same ingredients in different proportions, and of about the consistence of putty. A composition of the same sort, but containing more whiting than the first, is then brushed over it, and allowed to dry. This is repeated several times, till a considerable thickness has been laid on. The plain parts are then moistened, smoothed down with pumice stone and water, hard stone and water, Dutch rush, glass paper, and other substances; and the corners and mouldings are squared and shaped by proper tools. When dry the work is covered with several coatings of gold-size, a peculiar composition, of which deer's fat is said to form the principal ingredient. The frame or other article thus prepared, is placed in a sloping position; its parts are successively moistened with water; gold-leaf is laid on them by a "tip" (a sort of comb formed by inserting a row of camels' hairs into a card), and is pressed down into the cavities by a dry camel's hair pencil. The gold when dry is burnished by a stone in some parts; while others are left *mat* or dead, and are protected by a varnish of very clear size.

This constitutes *burnish-gilding*. *Oil gilding* differs from it chiefly in the use of a gold-size of an oily nature, which admits of no burnishing of the gold. *Japan-gilding* is a third kind, in which Japan gold-size is used, for work intended to be exposed to the weather.

The applications of gold-leaf to leather, paper, wood, and other substances, are numerous and diversified; but what has been said above will be sufficient to indicate the principles and details of this branch of the arts. It may be well to add, that glass may be gilt by the following simple method:—Dissolve some isinglass in water by means of heat; evaporate the liquid, and allow it to crystallise. Re-dissolve some of the crystals, and after making the mixture of the usual consistence of glue, dip into it a piece of clean chamois leather, which is to be drawn once, and only once, over the parts of the glass that are to be gilt. Lay on the leaf-gold, which will adhere, and allow the whole to dry. On this coating of gold another may be placed in a similar manner, being careful to draw the isinglass only once and lightly over the former coating. It will be generally found advisable to repeat this process a third time. Any superfluous gold may be removed by a sharp stick, and the gilt parts are to be polished by rubbing them with clean cotton, which will obliterate all traces of any joinings, and prevent them from being visible from either side of the glass.

GIN. [Cotton; Geneva.]

GIN, or **GYN**, a machine employed instead of a crane, chiefly by artillerymen, for the purpose of raising guns, howitzers, &c., on their carriages. It consists of three round poles, from 12 to 15 feet long, and 5 inches in diameter at the lower extremity, tapering to about 3½ inches at the top.

The three poles are, by means of an iron bolt passing through straps, or by a rope passed several times round each, united together at their upper extremities in such a manner that they may be turned about their place of union; and when the machine is set up, the feet of the poles are planted in the ground at about 8 or 9 feet from each other. The feet of two of the poles are kept at that distance by means of a rope or an iron bar, which may be temporarily placed in a horizontal position near their lower ends; and between the same two poles, at about 3½ feet from the ground, is a wooden roller, or windlass, which, by means of handspikes, may be turned on its axis, the pivots entering into holes sunk in iron cheeks attached to the poles. The third pole, commonly called a "pry-pole," has a greater extent of movement than the others about the upper extremity, so that all the three poles, previously to being set up, may lie on the ground. The gyn is then set up over the object to be moved; two blocks with their *fall*, or rope, are employed in raising or lowering the gun, the upper block being fixed to the top of the poles, and the other, by means of a rope, to the piece of ordnance: the rope from the upper block passes over the windlass before mentioned.

Two poles fastened together at the top, and set up like the sides of the letter A, the whole being kept steady by means of ropes made fast to the upper extremity and to strong pickets driven into the ground, are also employed for raising or lowering artillery, by means of two blocks with their rope, the extremity of the latter usually passing round the cylinder of a windlass, capstan, or crab. This apparatus is called sheers.

GIPSIES. [Gypsies.]

GIRDERS. The timber or iron beams, employed in building operations to carry loads over large openings, are known technically by the name of *Girders*, either simple or framed. The former will alone be noticed here.

A simple girder resists the action of the weight brought upon it by its inherent transverse strength, and it must be evident to any one who would observe the manner of fracture of any such beam, that the fracture is produced by the extension of the lower fibres, and by the compression of the upper ones, whilst the intermediate part of the beam plays but an insignificant part in its resistance, so long as the upper and the lower portions are not overstrained. Theoretically, then, the middle parts of a beam might almost be eliminated, because they not only do not render any service, but they actually tend to increase the load by their weight; but, from the physical nature of the materials usually employed as girders, it is hardly possible to attain this condition, and the efforts of the constructors are therefore limited to the attempt to approach, as nearly as may be, to the form of a girder of the maximum resistance with the minimum quantity of material. This form varies with every description of wood, or of iron; but the character of the growth of timber renders it unnecessary to pay much attention to the varying resistances of its fibres to compression or extension; whilst, on the contrary, it is easy to modify the disposition of the metal, whether wrought or cast, so as to call into play its various properties under the most economical conditions.

The strength of a simple timber girder is found, experimentally, to increase directly as the width, and as the square of the depth; or, if a beam of 6 inches on the sides bear a certain weight, two such beams will bear twice that weight, and a beam of twice the depth will bear four times the weight; the strength is likewise inversely as the length. These ratios are usually expressed by the formula $\frac{b\,d^2}{l}$, in which $b =$ the breadth, d the depth, and l the length; and it requires simply to be modified by a coefficient, dependent upon the specific strength of the kind of timber under consideration, to furnish a correct indication of the powers of resistance of a girder; or the breaking weight in pounds of a girder will be represented by $\frac{b\,d^2 c}{l}$, in which the new term, c, is the constant of the wood. Barlow, Nelson, Moore, and Dennison give, in the papers of the Royal Engineers, a table of constants which is now generally adopted; and from the fact that the results it indicates are considerably within the real capabilities of the various woods, there seems to be no reason for objecting to it:—

Kind of Wood.	Sp. gr.	Value of c.	Kind of Wood	Sp. gr.	Value of c.
Ash, English . .	·760	506	Pine, American, yellow .	·508	300

The manner in which a load is applied to a beam, it must however be observed, considerably modifies its resistance; for if the load be distributed equally over the whole length, the beam would carry twice as much as it would do if the load were concentrated in the centre. Again, if the ends of the beam be fixed, the breaking weight it would carry would be increased, upon the average, nearly in the ratio of 2 to 1. The values of c, given above, have been ascertained from the results of experiments on beams whose ends were loose; but as the effect of a permanent load (in producing fracture) is so markedly greater than that of an instantaneous load, it is not customary to take into account the increase of resistance of girders through the tying down of their ends, which in fact almost always occurs in building operations. The values of the above table are the instantaneous breaking weights of the average qualities of the woods named, and therefore the weight actually placed upon them should never exceed one-third of the amount they indicate; or, in other terms, the safety load of a beam should never exceed one third of the breaking weight. Buffon states that he had found that beams would break at the end of six months under two-thirds of the load they might be able to support for one day. It is essential also to observe that the character of the load will affect the resistance; for a dead weight produces a far less injurious action than would be produced by a rolling or a variable weight; and that the various kinds of wood yield in very different manners. Some of them deflect in an extraordinary degree, whilst others change but slightly in their outlines, and break suddenly, without warning, after their limits of elasticity have been exceeded.

The form of beams which is able to do the maximum amount of work with the minimum amount of substance is usually considered to be, according as the beam is supported at one or at both ends (Warr's 'Dynamics,' 1851), as follows:—For beams supported at one end; 1. *a.* If the load be constant, and applied at the extremity, and the depth of the beam be also constant, the transverse section should diminish gradually from the point of support towards the extremity; *b.* If the breadth be constant, the depth should vary as the length; if both breadth and depth vary, the vertical section should present a cubical parabola. 2. If the beam should only have its own weight to support, it should present in vertical section a double parabola, whose depth should be as the square of the length. 3. If the beam should be evenly loaded upon its surface, and the upper surface be horizontal, the lower surface should be a straight line meeting the upper surface at the extremity; the depth at the point of support being the one required to resist the effort of the load and of its leverage; and if an additional load be placed at the extremity of the beam, the under surface should present a parabolic curvature.

For beams supported at both ends:—1. If the beam be loaded at only one point, it should present a parabolic vertical section, falling each way from the loaded point. 2. If the beam be loaded uniformly, the upper surface should be elliptical, and the lower one straight. 3. In flanged beams evenly loaded, the upper surface should be made parabolic instead of elliptical, and the sides of the flanges in plan should also present a parabolic curvature.

In modern construction the openings between the points of support and the loads to be supported, are often so far in excess of the powers of wooden beams that it is necessary to resort to the use of iron in one or another of its forms; and, practically, this is effected by the use of some modification of the flanged section. Numerous experiments have been made for the purpose of ascertaining the best proportion to be given to metal girders, a description of which will be found in Warr's 'Dynamics' before quoted; in Barlow, on 'Materials and on Construction,' 1851; Moseley's 'Engineering and Architecture,' 1843; Weisbach's 'Mechanics of Engineering and Machinery,' 1848; Tate, on the 'Strength of Materials,' 1850; Fairburn, on 'Cast and Wrought Iron for Building Purposes,' 1854; Hodgkinson's new edition of Tredgold, 1856; Morin, 'Leçons de Méchanique Pratique,' 1846, &c. &c. From these authors it would appear, 1st, that the power of cast-iron to resist a tensile strain is, when compared to its power of resisting an effort of compression, as 1 to about 5·707; 2nd, that the strength of cast-iron girders is nearly in the direct ratio of their bottom flanges; 3rd, that everything else being equal, the strength is nearly as the depth. Mr. Fairbairn resumes the inquiry into the best form of iron girder by giving the following formula for ascertaining the breaking weight: $w = \frac{c\,a\,d}{l}$, in which w = the breaking weight applied in the centre; a, the area of the bottom flange, which is made 6 times that of the top one; d, the depth of the beam in inches; l, the distance between the supports in inches; and c, a constant, ascertained experimentally to be $= 26$. In the best cast-iron girders the proportions of the other respective parts than the top and bottom flanges are, *a.* the width of the bottom flange is made rather less than half the depth of the girder in the centre; *b.* the thickness of the centre web is made equal to one half that of the bottom web, when that theoretical condition can be attained without compromising the solidity of the casting, or the quality of the metal.

Compound cast-iron girders, in which the strength is obtained by a combination of the resistances of cast and wrought iron, have been found practically to be liable to so many objections, on account of the different physical properties of the two states of the metal, as to have led to the abandonment of their use. Cast-iron beams are frequently cast in lengths of 40 feet, and even occasionally of 70 feet, though at some risk. Beyond those lengths, it is necessary to resort to the use of either the arched construction, if cast-iron be used, to some description of framed girder, or to the use of wrought iron.

In wrought-iron girders it is found that the proportionate resistance of the top and bottom flanges to the efforts of compression and extension differ notably from those which were previously stated to prevail in cast-iron; for the resistance of wrought iron to compression is only one half of its powers to resist extension, and the top flanges of wrought-iron girders, therefore, should be made about double the sectional area of the bottom flanges, instead of being as in cast-iron girders only $\frac{1}{6}$ of that dimension. Mr. Fairbairn gives the formula for the breaking weight of a wrought-iron girder, as follows; $w = \frac{a\,d\,c}{l}$, in which the same notation is followed as in the formula for cast-iron girders; but singularly enough in working out his examples, instead of making a = the *area* of the bottom flange, he attributes to it a value derived from the *width*. The coefficient, c, becomes, according to Mr. Fairbairn, 75, when ordinary plate-iron girders are used, and 80, when boxed girders are adopted; and, from the experiments he records, it would seem that the coefficient of a lattice girder is nearly the same as that of a plate girder. Exactly, it would appear to be 72. One of the best rules for proportioning box girders is, firstly, to make the area of the top equal to twice that of the bottom; to make the thickness of the sides from $\frac{1}{70}$ to $\frac{1}{300}$ of the depth of the tube, according to the facilities for giving it lateral stiffness; and then, as the span and the depth are often given, to calculate the dimensions of the bottom flange from the ratio, $s : d :: s : w$; in which s = the span; d = the depth; s = the cohesive strength of the bottom flange, calculated on the assumption that it is equal to 15 tons on the superficial inch; and w = the breaking weight in tons. This would, of course, give the weight under which the girder would instantaneously break, and it should therefore never be approached in practice. Indeed, if the girder should be exposed to rolling weights, or to sudden shocks, it should present a resistance at least six times that of the maximum load able to produce instantaneous fracture.

The above remarks have been designedly made as practical, and as devoid of abstract theory as possible, leaving that part of the investigation to RESISTANCE OF MATERIALS; NEUTRAL AXIS; TUBULAR BEAMS. The reader who may desire to study the theory of the subject is, moreover, referred to the author before quoted; or to Clark's 'Britannia and Conway Tubular Bridges.' Framed girders are described under TRUSS.

GIRDLE, a band of leather, or some other substance, to gird up the loins: from the Anglo-Saxon *gyrdel* or *gyrdl*, and that from *gyrdan*, to encircle or bind around. Girdlestead is an old English word for the waist, or place of the girdle.

There are many passages in Scripture, as well as among the Greek and Roman writers, illustrative of the girdle. It appears to have been rarely worn by the Hebrews, except upon a journey. Elijah, we are told, girded up his loins, and ran before Ahab. Girdles of sackcloth, too, were used among the Hebrews as marks of humiliation and sorrow.

As a military ornament, it is noticed in Homer ('Il.' iv. 135; v. 539, &c.); and so universal was its use among the Greek and Roman warriors, that Pitiscus, in his Lexicon, says, "Et *Cingulum* pro ipsa militia usurpatur." Military girdles were often given as rewards for bravery. The magister equitum of the Romans wore a red girdle as a distinctive badge.

A girdle, or zone, was always worn by young women before marriage. Hence, "Zonam solvere virgineam," to loose the maiden's girdle, in the language of Catullus, was a phrase appropriate to the marriage ceremony. Festus says, "Cingulum quo nupta cingebatur vir in lecto solvebat." This girdle was usually of wool. The cestus of Venus was the zone or girdle. It was worn round the lower part of the waist, and concealed by the falling of the tunic.

The term girdle was in ancient times very frequently used to express the purse. An epigram in the 'Anthologia' shows that this was the custom among the Greeks; and it is in this sense that we must understand the fragment of Gracchus's speech to the senate, upon his return from Sardinia, quoted in Aulus Gellius, lib. xv., c. 12: "Itaque Quirites, quum Romam profectus sum, zonas, quas plenas argenti extuli, eas ex provincia inanes retuli."

In Mark vi. 8, when our Saviour sent his Apostles out to preach, he commanded them to take no scrip, no bread, no money in their purse: the Anglo-Saxon version reads, *ne fesh on hyra gyrdlum*, "nor money in their girdles." Hence probably arose the custom, formerly used in England, for bankrupts or other insolvent persons to put off and surrender their girdles in open court.

Various passages in the classic writers might be adduced to show that to go without the girdle was considered disreputable, and bespoke a dissolute person. Aubrey, in one of his manuscripts, says that "Ungirt, unblessed," was an English proverb before the civil wars of Charles I.

Among the ancient companies of London, that of the Girdlers was incorporated as early as August 6, 1449, 27 Henry VI., and it has been supposed that these were the makers of girdles. Their armorial ensigns are, "Per fess, az. and or, a pale counter-changed, each piece of the first charged with a gridiron of the second. Crest, the demi-effigy of St. Lawrence, holding in the right hand a gridiron, and in the left a book." Strype, in his edition of Stow's 'Survey,' conjectures, from their arms, that the girdlers were originally a fraternity of St. Lawrence. But, as Mr. Thoms, in his edition of Stow, suggests, these arms seem to indicate pretty clearly that the girdlers were really makers of the girdles, or griddles, still used for baking oaten cakes in every household in Scotland and much of the north of England.

GIRONDINS was the name given to a political party which formed a section of the second National Assembly of France, called "Legislatif," in contradistinction to the first or "Constituante," which framed the constitution of 1791. The members of this party were mostly returned by the departments of the west and south; and as their leaders, Vergniaud, Guadet, Gensonné, &c., represented the department of La Gironde (Bordeaux), the party took the name of Girondins. They showed themselves from the first hostile to the monarchy, and they stood opposed to the constitutionalists, who wished to maintain the constitution of 1791. The Girondins were republicans, who had formed notions of liberty on classical models, such as they were then conceived by ardent young men. They had among them some brilliant orators, and several accomplished and amiable individuals; but as a political party they placed themselves in a false position, and they did great mischief to others. By their opposition to the constitutionalists they weakened the strength of the middling classes, and left the field open to those who, like Danton, addressed themselves to the passions of the lower orders. They at one time obliged the king to choose a ministry from among themselves, including Roland, Servan, Clavière, and Dumouriez, and they seemed for awhile reconciled to the constitutional monarchy; but a schism broke out among them, and they resigned. Soon after came the scenes of June and August, 1792, which the Girondins indirectly sanctioned, and which destroyed the monarchy in France. In the Convention the Girondins for the most part voted for the death of the king; they tried indeed to obtain a reprieve for him, but in this they failed. They then began to feel their weakness; they struggled for several months against the ascendancy of the Montagne or Terrorist party, which was supported by the mob; the Girondins wished for legal forms, they denounced the popular massacres, but they had no support out of doors to depend upon. At the same time they excited the republican enthusiasm of the French, and it was Brissot, one of their leaders, who proclaimed the principle of democratic proselytism, afterwards sanctioned by the Convention, by its decree of the 17th of December, 1792. But this turned to the profit of the Terrorists at home, who were the men of the lower classes, which the Girondins were not. The latter endeavoured to create an opposition in the departments, to counterbalance the influence of the Paris demagogues, but they were denounced as wishing and conspiring to split France into as many republics as there were departments. At last, on the 31st of May, 1793, the Convention was assailed by armed multitudes, demanding the imprisonment of twenty-nine deputies of the Girondin party. The Assembly was obliged to give them up, and on the 31st of October following twenty-one of them were executed, including Vergniaud, Gaudet, Gensonné, and Brissot. Others were beheaded afterwards. A few escaped, and reappeared again in the Convention after the fall of Robespierre. Dumont, in his 'Recollections of Mirabeau,' ch. 18–20, gives some vivid sketches of several of the leaders of the Girondins; and Lamartine has written a 'History of the Girondists.'

GITHAGIN, a peculiar kind of Saponin, obtained from the corn lychnis (*Lychnis githago* and *Agrostemma githago*). [SAPONIN.]

GLACIS, an elevation of earth surrounding a fortress on the exterior of the covered-way, to which it serves as a parapet. [s, s, *fig.* 1, BASTION.] Its crest is eight feet above the terreplein of the covered-way, and its superior surface, which descends with a gentle slope towards the country, meets the natural ground at about fifty yards from the covered-way.

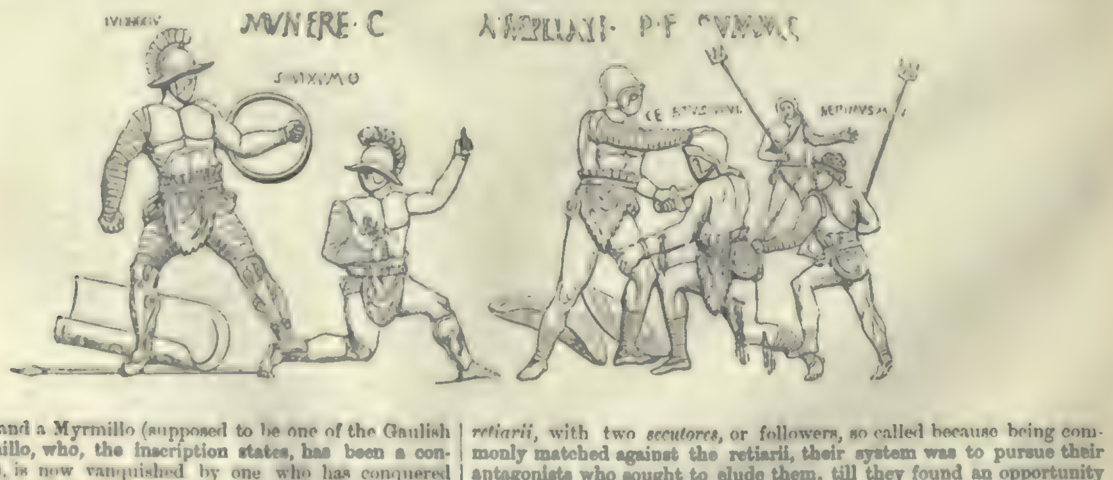
The glacis conceals the upper part of the masonry of the escarp from distant breaching batteries, and by forming an inclined plane ascending towards the fortress, serves to expose the approaches of the besiegers, when they arrive near the place, to the fire of artillery from the bastions or ravelins; and a banquette, or step, at the foot of its interior slope, enables the defenders to graze its superior surface by a fire of musketry, and gives the further defence of another line of simultaneous fire.

Any elevation of earth beyond the ditch of a fortress, and forming an inclined plane descending towards the latter, is called a reverse or counterslope glacis.

GLADIATORS were men who fought with swords, 'gladii,' and other weapons, and wounded and killed one another in the circus, the amphitheatre, and other public places, for the entertainment of the Roman people. They were either slaves, prisoners or convicts, and as such obliged to fight; or volunteers, who exhibited for money. There were establishments in the Roman towns, in which the gladiators were boarded and taught their art, and in which a certain number of those who had been trained were always kept in readiness for the fight. Their master and keeper was called Lanista. Gladiators were classed and named according to the weapons they used, and their manner of fighting: thus *Ordinarii* were those who fought in pairs in the ordinary way; *Catervarii*, those who fought several together; *Equites*, those who fought on horseback; *Retiarii*, those who used a sort of fork called a tridens, and a net which they threw over their opponent, who usually carried a short sword and shield; *Andabatæ*, who fought blindfold, their heads being covered with helmets which had no apertures, and whose manœuvres were consequently exceedingly ludicrous; *Hoplomachi*, who fought in complete armour, &c. All bore armour on the right arm, if nowhere else; and except the Retiarii, wore helmets, and carried shields. The *Bestiarii*, who fought with wild animals for money, were not ranked among the gladiators. When a wealthy man wanted to give a gladiators' fight, either at a funeral or on any other public or private occasion, he bargained with the Lanista for a certain price to give him so many pairs of gladiators. Out of each pair one was to die, if so required by the spectators. Palms were given to the victors. When a gladiator was severely wounded, so as to be unable to fight any longer, his antagonist stood over him with his sword ready to kill him, and looked up to the assembly for its fiat. If the majority turned their thumbs downwards, that was the signal of death. The origin of this barbarous custom seems to have been derived from the practice of killing a certain number of captives at the funeral of a chieftain. Homer represents Achilles as sacrificing twelve young Trojans at the funeral of his friend Patroclus. Afterwards, instead of butchering the prisoners like so many cattle, it was thought better to make them fight round the funeral pyre, when the conquerors had a chance of escaping with their lives. By degrees the custom was extended to all great festivals, for the amusement of the spectators, and the waste of human life thus wantonly sacrificed was increased to a fearful extent in the later times of the Roman republic and under the empire: on the occasion of Trajan's triumph over the Dacians 10,000 gladiators are said to have fought. The practice was defended even by grave men, and Cicero among the rest, as serving to keep up a martial spirit and a contempt of death among the people. It certainly contributed to render the people ferocious and cruel. Constantine prohibited gladiators' fights by an edict ('Cod.' xi., tit. 43), but the practice, it is said, was not totally extinct in the West till the time of Theodoric. The Greek republics did not adopt the custom of gladiators' fights. It was a practice essentially Roman, and the Romans are said to have adopted it from the Campanians, who had gladiators' fights even at their banquets. (Lipsius, 'Saturnalia;' Ferrari Octavius, 'Dissertatio de Gladiatoribus.')

Rome was at one time near paying very dearly for this inhuman pastime. In the year 76 B.C. seventy-four gladiators at Capua rose against their master, overpowered the guards and fled to the mountains, where they were joined by runaway slaves and peasants, to the number of several thousands. Being led by a gladiator of the name of Spartacus, a Thracian by birth and a man of superior abilities, they defeated several Roman armies, overran Campania, Lucania, and other provinces, took and plundered Nola, Nuceria, and other towns, and spread alarm almost to the gates of Rome. But dissension grew up among their ranks. One portion of them, chiefly Gauls, separated from the rest under one Crixus, and were defeated and cut to pieces by the consul Gellius. Spartacus, who was on his march towards North Italy, having retraced his steps on hearing this news, defeated Gellius, as well as the other consul Lentulus, and then fortified himself in the mountains of Lucania. He performed a solemn funeral in honour of Crixus, who had fallen in battle, and obliged 300 Roman captives to fight as gladiators round the pyre. The war lasted three years, at the end of which Spartacus was defeated by the prætor M. Crassus, and was killed after performing prodigies of valour. (Livy, 'Epitome,' 95–97; Eutropius, vi. 6.) [CRASSUS, in BIOG. DIV.]

There are several ancient statues, highly praised for their workmanship, which represent or are supposed to represent gladiators in several attitudes. One of the best is the 'Fighting Gladiator' of the Borghese collection, now in the Museum of the Louvre. The 'Dying Gladiator' of the Capitoline Museum has furnished Byron with the subject of one of the finest stanzas of his 'Childe Harold:' "I see before me the Gladiator lie." In the tomb of Scaurus at Pompeii is a series of bassi-relievi, which aided by the inscriptions placed above each group, illustrate very clearly the manner of fighting of the gladiators. The annexed cut is from a portion of the upper frieze. The pair on the right are a Thrax (Thracian) and a Myrmillo (supposed to be one of the Gaulish tribes). The Myrmillo, who, the inscription states, has been a conqueror fifteen times, is now vanquished by one who has conquered thirty-four times; he begs his life, but the letter Θ (the initial of θανων) indicates that he was to be put to death. The other group are two *retiarii*, with two *secutores*, or followers, so called because being commonly matched against the retiarii, their system was to pursue their antagonists who sought to elude them, till they found an opportunity to cast the net. In this case, a secutor has been defeated, and pleads for mercy; the spectators however have turned down their thumbs, but as



the trident with which the retiarius is armed is not a weapon fitted for speedily despatching a man, the poor wretch's fellow secutor, Hypolitus, has to perform this last office, prior to encountering in his turn another retiarius, who is seen waiting in the distance.

GLAIRIN; *Baregin*; an azotised matter found in the water of hot sulphureous springs. It has been compared to albumen and gelatin, but its composition differs considerably from these bodies. It consists of,—

Carbon	45·20
Hydrogen	6·95
Nitrogen	5·60
Ash	40·70
Oxygen	1·55
	100·00

GLANDERS, or *Farcy*, is a name given by veterinary surgeons to a disease affecting horses and other cattle. It appears in the form of a suppurative disease of the mucous membrane of the nose and of a pustular eruption. The former is sometimes called glanders and the latter farcy, but the two often occur together, and the pus discharged by the one will produce the other. In 1821, Mr. Muscroft drew attention to the fact that this disease could be communicated from the horse to the human system. In the same year cases occurred in Germany, and since then it has been demonstrated by a large number of cases that this disease often spreads from the horse to man. When it attacks man it is characterised by vascular injection of the nasal mucous membrane, on which chancre-like sores are formed, extending to the frontal sinus and neighbouring mucous surfaces, from which a profuse and offensive discharge flows. At the same time a tubercular or pustular eruption appears upon the skin, followed by suppurating bloody or gangrenous ulceration in various parts. These symptoms may be either *acute* or *chronic*. In the acute cases a primary fever is followed by the local disease. In chronic cases the local affection alone presents itself. The acute disease is ushered in by rigors, pains in the back and limbs. These symptoms are followed by phlegmonous tumours in various parts of the body, which are accompanied with pain and tenderness, and terminate in abscesses or boils. At the same time a discharge takes place from the nostrils of a matter more or less purulent, viscid, and mixed with blood. The eyelids frequently become tumefied, and discharge a thick viscid matter like that from the nose. About the twelfth day of the disease an eruption breaks out on the face, trunk, and limbs. It is preceded and accompanied by profuse and fetid sweats. The eruption is scattered, and resembles, according to circumstances, the vesicles of cow-pox, or the pustules of small-pox or ecthyma. These are sometimes accompanied with large vesicles (bullæ), which become black, and discharging leave gangrenous sores. At first the pulse is full and quick; but it becomes rapid, small, irregular, and intermittent. The tongue is at first loaded with white fur, which afterwards becomes brown or black. Diarrhœa and tympanitis often come on in the course of the disease. This disease is generally fatal from the seventeenth to the twenty-first day. In the chronic cases the febrile symptoms are not so prominent. The local symptoms are much the same, but they progress more slowly. The abscesses are attended with a large amount of subcutaneous inflammation. A twelvemonth has been known to elapse in such cases as these before a patient has recovered or died.

There is no doubt that these symptoms are the result of a poison introduced into the system of man from the horse. In all cases contact with glandered horses has been ascertained to have taken place before the breaking out of the disease. Matter has been taken from the ulcers and membranes in men, and horses have been inoculated, and the disease has been produced. The disease has also been produced by compelling animals to swallow the poisoned matter in their food. There can, therefore, be no doubt that the poison can be absorbed both from mucous and cutaneous surfaces. This being ascertained, it becomes more than ever necessary to prevent contact with glandered horses. Such horses have been known to give the disease to persons riding behind them or passing near them by snorting the matter from their nostrils into the air. All glandered horses ought to be destroyed. In Germany the conviction of the danger of this disease is so strong, that all horses proved to have come in contact with glandered horses are ordered to be destroyed. Not only can this disease be communicated from horse to horse, and from the horse to man, but cases have occurred in which those attending glandered individuals have become affected. The poison of glanders soon manifests itself. Mr. Turner inoculated two young donkeys, and in one the maxillary glands became tender on the second day, and the discharge took place from the nose on the third day, whilst in the second the glands became swollen on the third day, and the discharge took place on the sixth. Cases have been recorded in which the incubation of the poison must have taken at least three months. In the human being the poison has remained latent from two to eight days after exposure.

This disease in its acute form is very fatal. Of fifteen cases recorded by Rayer only one recovered. Of the treatment, therefore, little can be said as a matter of experience. The general symptoms in the latter stages are those of low malignant fever, and a stimulant plan of treatment is indicated. Cases have been bled and cupped, and the blood was buffed, but there is no reason to believe that the bleeding did any good. In the chronic forms of the disease recovery is more frequent. The symptoms indicate the necessity of a generous diet.

We add the following remarks by Mr. Finlay Dun, V.S., in the 14th vol. of the 'English Agricultural Society's Journal,' pp. 128, 129:—

"From their weak and unsound constitution, horses of a scrofulous diathesis are unusually prone to *glanders* and *farcy*—two forms of a disease peculiar (at least as an original disease) to the equine species. As has been already remarked, it is characterised by a specific unhealthy inflammation, identical in all important characters with the syphilitic inflammation in man. From the dire and loathsome nature of glanders, and the terror in which it is held, animals affected by it are never used for breeding, so that we have little opportunity of judging of its hereditary nature. There is no evidence (so far as I know) which proves it to be directly hereditary, but there is no doubt that the progeny of a glanderous horse would exhibit an unusually strong tendency to the disease. Though I am not aware of any facts proving glanders to be congenital, yet I think there is every probability that such is the case; for it is notorious that syphilis, the analogous disease in the human subject, is congenital, and often appears at birth in the children of women affected by that disease. Its ordinary predisposing causes are, many of them, hereditary: it is very prone to attack animals of a weak or vitiated constitution. It is emphatically *the* disease which cuts off all horses that have had their vital energies reduced below the healthy standard, either by inherent or acquired causes. Glanders is also sometimes caused by inoculation; is frequently produced in healthy subjects by mismanagement, as by insufficient food, want of shelter, and overwork; and often supervenes on bad attacks of influenza, strangles, diabetes, and other diseases which debilitate the system, or impair the integrity of any of its more important parts. These causes appear to possess the power of engendering in the constitution of the horse a peculiar poison, which, as it reproduces itself, and spreads to all parts of the body, gives rise to the characteristic symptoms of glanders, causing, sooner or later, a breaking up of the system, and a fatal prostration of the vital powers. This poison produces in the blood abnormal changes, which vitiate that fluid, and unfit it for healthy nutrition. From the irritant action of the morbid fluids passing through them, the lymphatic glands and vessels become inflamed, and lymph is deposited. This, however, being of an unhealthy nature, soon runs on to softening, which extends to the skin overlying the part, and ulcerating farcy-buds are formed. On the surface of the more vascular mucous membranes effusions of tubercular matter are also poured out; these take on an unhealthy inflammation, and degenerate into chancrous ulcers, which may generally be seen on the mucous membrane of the nostrils in most bad cases of glanders."

GLASS MANUFACTURE. Glass, one of the most beautiful of manufactured products, is a transparent, solid, and hard substance, exceedingly brittle while cold; but by the application of a high degree of heat it is rendered so flexible and tenacious that it may with the utmost facility be moulded into any form. It is so ductile while heated, that it may be spun into filaments of the greatest conceivable fineness; and these when cold are exceedingly pliant and elastic.

The time at which glass was invented is very uncertain. The popular opinion upon this subject refers the discovery to accident. It is said (Plin. 'Nat. Hist.' lib. xxxvi., c. 26) "that some mariners, who had a cargo of *nitrum* (salt, or, as some have supposed, soda) on board, having landed on the banks of the river Belus, a small stream at the base of Mount Carmel in Palestine, and finding no stones to rest their pots on, placed under them some masses of nitrum, which, being fused by the heat with the sand of the river, produced a liquid and transparent stream: such was the origin of glass." The ancient Egyptians were certainly acquainted with the art of glass-making. This subject is very fully discussed in a memoir by M. Boudet, in the 'Description de l'Egypt,' vol. ix., Antiq. Mémoires. The earthenware beads found in some mummy cases have an external coat of glass, coloured with a metallic oxide: and among the ruins of Thebes pieces of blue glass have been discovered. Sir Gardner Wilkinson adduces three distinct proofs that the art of glass-working was known in Egypt before the exodus of the children of Israel from that land, more than 3500 years ago. The manufacture of glass was long carried on at Alexandria, from which city the Romans were supplied with that material; but before the time of Pliny it had been introduced into Italy, France, and Spain (xxxvi., c. 26). Glass utensils have been found among the ruins of Herculaneum.

The application of glass to the glazing of windows is of comparatively modern introduction, at least in northern and western Europe. In the year 674 artists were brought to England from abroad to glaze the church windows at Weremouth in Durham; but even in the year 1567 this mode of excluding cold from dwellings was confined to large establishments, and by no means universal even in them. An entry then made in the minutes of a survey of Alnwick Castle, the residence of the Duke of Northumberland, informs us that the glass casements were taken down during the absence of the family, to preserve them from accident. A century after that time the use of window-glass was so small in Scotland that only the upper rooms in the royal palaces were furnished with it, the lower part having wooden shutters to admit or exclude the air. It may be presumed that this window-glass was of home-make. The earliest manufacture of flint-glass in England was begun in 1557; and the progress made in perfecting it was so slow, that it was not until near the close of the 17th century that this country was independent of foreigners for the supply of the common article of drinking-glasses. In 1673 some plate-glass was made at Lambeth, in works supported by the Duke of Buckingham, but which were soon abandoned. It was exactly one century later that the first establishment of magnitude for the production of plate-glass was formed in this country, under the title of "The Governor and Company of British Cast Plate-glass Manufacturers." The members of this company subscribed an ample capital, and works upon a large scale were erected at Ravenhead, near Prescot in Lancashire, which have been in constant and successful operation from that time to the present day.

There are several distinct kinds of glass, which differ from each other in regard to some of the ingredients of which they are made, and in the processes of manufacture. The names *crown, flint, cut, window, sheet, broad, spread, blown, cast, plate*, &c., glass, are not very well chosen; but whatever be the names, the principal ingredients employed are silex or flint, and an alkali. The differences in the various kinds result from the description of alkali employed, and from the addition of certain accessary materials, usually metallic oxides. The form in which silex is now generally used in this country for glass-making is that of sea-sand, and care is required to select those kinds which are free from foreign matters and impurities. The port of Lynn in Norfolk, and Alum Bay in the Isle of Wight, have long furnished the greater part of the silex used in our glass-houses. Flint-glass derives its name from the practice in former times of using flints calcined and ground in the manner now employed for making porcelain; but this has long been discontinued. Of late there has been some apprehension of a scarcity of sand suitable to the manufacture; and a good idea may be formed as to the importance attached to the purity of this chief ingredient from the fact that sand has been imported for the purpose from New South Wales. The alkali employed for making fine flint-glass is pearl-ash, purified by solution and subsidence, in which process impurities to the extent of one-third of the weight are removed. Coarser alkaline substances are used for making inferior kinds of glass: the impurities even assist towards fusing the silex; but such alkalies all contain iron in some degree, and it is to the presence of this metal that the green colour of common glass is owing. Barilla and kelp were formerly the chief sources of the soda employed; but in recent years the carbonate and sulphate of this alkali have been obtained from common salt; either one alone, or the two combined, being chosen for different kinds of glass.

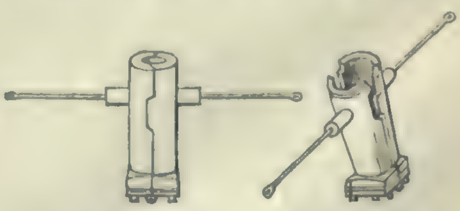
We shall now treat succinctly of the processes by which the principal kinds of glass are produced.

Flint Glass. This, known in other countries under the name of crystal, is the most generally useful, the most brilliant, and the heaviest description of glass. This last quality it owes to the large quantity of oxide of lead which it contains, and which is used sometimes in the form of minium, but more frequently in that of litharge. The metallic oxide acts as a flux, and promotes the fusion of the other materials at a comparatively low temperature. The greater density which it imparts gives to the glass a greater power of refracting the rays of light; and it is this quality which renders flint-glass of so much importance for optical purposes. Nitre in a small proportion is used for the destruction of any carbonaceous matter in the other ingredients; the oxygen which it gives out in the furnace further serves to maintain at their highest degree of oxygenation the metallic oxides that are present. Black oxide of manganese in minute proportion is also used to remove any foul colour that might otherwise remain through the impurity of the alkali used; its cleansing property occasioned this oxide to be known formerly under the name of glass-soap. Any undue proportion of manganese would impart a purple hue to the mass; and if any considerable quantity be used that colour will be deepened almost to black. When through inadvertence the glass has been made purple, the colour will be almost instantly discharged by thrusting a piece of wood into the melted mass. The cause of these changes is as follows:—The purple colour given by oxide of manganese arises from its being in a high state of oxygenation; the wood when thrust into the heated mass becomes speedily carbonised, and the carbon, combining with the superfluous oxygen, is driven off in the form of carbonic acid gas; if by the addition of nitre the quantity of oxygen is again increased, it will combine with the manganese, and restore the purple colour. It will be seen from these circumstances how much skill and experience are necessary for the due mixture of ingredients so as to produce glass of the best quality. The manufacturers of flint-glass are generally unwilling to disclose the precise proportions in which they employ the requisite ingredients; and it is probable that each has a favourite recipe of his own. One kind consists of 120 parts fine clean white sand, 40 well-purified pearl ash, 35 litharge or minium, 13 nitre, and a small (undefined) quantity of the black oxide of manganese. The French chemists recommend a much larger proportion of oxide of lead, but this is found to make the glass inconveniently soft. Where less metallic oxide is used, more nitre is required as a flux, and *vice versâ.*

The ingredients, in whatever proportions selected, must all be intimately mixed before they are put into the crucibles or pots, which are previously placed in the furnace. These pots are very carefully made of Stourbridge clay; they are about a yard in height, with only one arch-shaped opening at the side, and each will contain 16 cwt. of glass. As the bulk decreases by fusion, fresh portions of the ingredients are added until the pots are full of melted glass. A very strong and long-continued heat is necessary, not only for the perfect fusion and amalgamation of the materials, but also for the discharge of the impurities which they contain. The chief of these, known under the name of sandivir, or glass-gall, consists of salts existing in the alkali which have but small affinity for silex, and from their specific levity rise in the form of a white porous scum to the top of the crucible, whence it must be removed before it is volatilised by the excessive heat of the furnace. This glass-gall is used as a powerful flux by refiners of metals. When the whole of the impurities have been thus thrown off by the action of heat and are removed, and the glass, or *metal*, as it is called, appears colourless and translucent, the vitrification is known to be complete. The temperature of the furnace is then lowered by preventing the access of air until the glass loses a part of its fluidity, and assumes that pasty character which is the most convenient for the workmen; it being sufficiently consistent to be tenacious, but soft enough to yield to the slightest pressure without cracking or losing its tenuity. The material is usually brought to a perfect state of vitrification in about forty-eight hours from the first application of heat.

Melting-pots for Flint-glass.

There is perhaps no process of manufacture which more excites the surprise and admiration of a stranger than that of fashioning flint-glass into all the various objects of convenience and ornament for which it is employed. To see a substance, proverbially brittle, blown with the human breath, pulled, twisted, cut, and then joined again with the greatest facility, never fails to strike with astonishment those who are unaccustomed to the sight. The tools with which all these operations are performed are of the most inartificial description, and do not appear to have received any improvement from the earliest records of the manufacture. Most articles in flint-glass, such as drinking glasses, cruets, decanters, phials, &c., are made by the combined processes of blowing, manipulation, and casting, in varying degrees. A square perfumery bottle may be selected as an example of one kind. The workman takes a long iron tube, and collects a little of the melted glass on one end of it, by thrusting the tube through the open door of the furnace into the mouth of the melting-pot; this pasty glass is rolled into a cylindrical form on an iron plate, and is pinched at one place to form a neck. The glass is then thrust into a brass or iron mould, and the workman blows through the other end of the tube; the mould gives an external shape to the glass, while the current of breath hollows the interior. All this is done in less than half a minute. The mould, which consists of two halves hinged together, is opened; the glass is taken out; it is detached from the tube by a touch with a piece of cold iron; it is taken up on the end of a heated rod by another workman; and by means of a few simple tools the neck and mouth of the bottle are finished. A claret-jug may be taken as an example of another large class of flint-glass manufactures. The workman collects a considerable quantity of melted glass on the end of his iron tube, which is raised to elongate it, rolls it into a cylin-



Moulds for casting Flint-glass bottles.

drical shape, and blows through at the other end of the tube. Another workman then takes it; and by a combined process of blowing, rotating, and manipulation with small tools, the mass of glass gradually assumes the form of a jug, without being cast or pressed into any mould. A small quantity of glass is added and speedily fashioned into a foot for the jug, and another similarly for the handle. All these operations are effected with surprising quickness and precision. The glass is in such a medium state between solid and liquid, that while, on the one hand, it would drop from the tube if not kept rotating, it is, on the other, susceptible of being pulled, stretched, cut, pressed, and worked in various ways. The workman has nothing but his hand and eye to guide him in giving accuracy of shape to the article manufactured. The facility with which an additional piece attaches itself to and becomes part of the larger mass, enables the workman to supply all such appendages as the stems and feet of wine-glasses, the handles and lips of jugs, &c.

Blowing for Flint-glass.

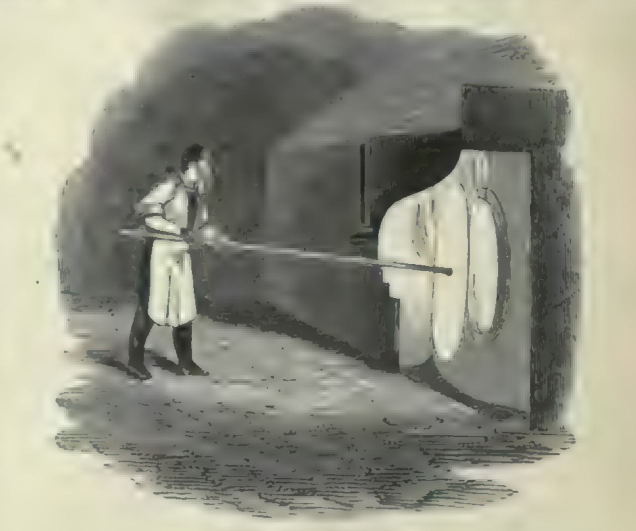
Flint-glass working.

Flint-glass is used for a large variety of purposes, and many adjustments of the manufacturing processes are found necessary. *Thermometer* and *barometer tubes* are made by an operation which depends on the remarkable ductility of glass. A workman collects a quantity of glass on the end of a tube; rolls it on an iron plate into a cylindrical form; blows into it to form a cavity within; and attaches the other end to a heated rod. Two men—the one holding the tube and the other the rod—then walk backwards, stretching out the tube of glass to a length of 40 or 50 feet. One of the most remarkable circumstances connected with this operation is, that the hollow within the glass retains exactly the same shape, although the mass may be extended from a few inches to 50 feet in length; and the workman can thus obtain either cylindrical or flattish tubes, as may be required. The tubes are broken into smaller lengths for use. In making *glass beads*, a very fine and narrow tube of glass is taken, and one end is placed in the flame of a lamp while the workman blows in at the other; he expands the heated end into a small hollow sphere by the action of his breath, and then breaks it off. So rapidly is this done, that one workman can produce five or six thousand in a day. Some of these beads, made of coloured glass, are used for necklaces; some, carefully treated afterwards, become *dolls' eyes;* while others, made of a slightly bluish-white glass, become *artificial pearls*, by being coated on the inside with pearl-essence, or essence d'Orient, a liquid prepared from the scales of the blay or bleak fish. The substance called *avanturine glass*, a Venetian product, is applied to the manufacture of trinkets and ornaments, and is named, on account of its resemblance to the natural crystal, avanturine. It is a yellowish-brown glass, inclosing fine thin yellow laminæ or scales of a brilliant metallic lustre. The manufacture is not well understood in England. Some think that the yellow laminæ are produced by melting scales of meta or mica with the glass; but it is deemed more probable that a salt of copper is mixed and melted with the glass, and that a powerful reducing agent decomposes this salt during the melting, and separates the copper in the state of thin metallic scales. *Venetian* and *Bohemian glass* are in general illustrations of the great diversities which can be produced in glass, by adding metallic oxides to produce colour, and by a peculiar treatment of the finishing processes; but the rationale and general character of the manufacture are sufficiently denoted by the description given above. The fanciful productions known by the names of *Venetian ball, Venetian filagree, Milléfiore glass, Mosaic glass, Smetz glass, Vitro di trino*, &c., are all specimens of flint-glass which have undergone peculiar treatment. *Optical glass* is mostly flint-glass, although the different refrangibility of other kinds leads to the combination of two or more in producing achromatic and aplanatic lenses. But, in truth, opticians care little about the name given to their glass; they have long been trying, and still are trying, to produce pieces large enough for telescopes of great diameter, and perfectly free from specks or blemishes; and if they succeed in this, it matters little whether the substance more nearly resembles flint, or plate, or crown glass. Mr. Cooper, a glass-manufacturer at Aberdeen, sent to the Scottish Society of Arts a few years ago two recipes for optical glass, which he had found advantageous. The first consisted of well-washed and sifted sand, 60 parts; oxide of lead, 60; purified carbonate of potash, 15; saltpetre, 3½; and broken flint-glass, 15 to 20. Another kind, heavier and of greater refrangibility, was composed of sand, 60 parts; oxide of lead, 63; carbonate of potash, 14; saltpetre, 3½; and broken flint-glass, 20. In 1854, M. de Peyrony submitted to the Académie des Sciences a proposal for a new mode of making optical glass for large lenses. In the usual way, the mass of glass having been brought to a state of fusion in the crucible, the material is simply stirred to make it homogeneous, and to drive out the included bubbles of air. But this double object is never completely attained; for the stirring itself occasions the formation of striæ, or waving lines, which necessitate the rejection of a large portion of the glass taken from the crucible, as being unfitted for the formation of lenses. Hence the difficulty of obtaining lenses of large diameter. M. de Peyrony proposed to give the crucible a motion of rotation around a vertical axis; the centrifugal force, he suggested, would unite the air-bubbles towards the centre of the mass, while the striæ made by the stirring would for the most part disappear; those that remain would probably assume a circular form, and would produce little inconvenience, provided the optician took care to make the axis of the mass coincide with that of the lens. The finest optical glass yet produced, perhaps, is a telescope-lens which was shown at the Paris Exhibition in 1855. M. Lelebours obtained the piece of glass from the glass-works at Choisy-le-Roi, and bestowed some months of labour upon it; it is 14 English inches in diameter. The French government bought it for what was considered by scientific men an inadequate price,—25,000 francs, or 1000*l.*; and it is now fitted into the finest telescope at the Paris Observatory. At the same Exhibition, Messrs. Chance, the glass-manufacturers of Birmingham, brought forward, not lenses, but discs of glass intended for lenses, of a size never before equalled. The discs were made, some of flint, and some of crown-glass; two of them were *twenty-nine inches in diameter* each. Sir David Brewster urged the British government to purchase these discs, and therewith to make "the greatest achromatic telescope that was ever contemplated by the most sanguine astronomer;" but without success.

Flint glass, for domestic and ornamental purposes, undergoes many processes after the moulding and shaping; such as annealing, cutting, engraving, gilding, &c. The process of *annealing*, intended to lessen the brittleness of the glass, is noticed under ANNEALING. The *cutting* consists in a grinding away of portions of the glass, to produce that peculiar effect which is familiar to every one in cut-glass. This is done by means of small wheels, made of cast-iron, wrought-iron, Yorkshire stone, willow-wood, and other substances. Each wheel is made to revolve very rapidly on a horizontal axis; the edge or periphery is that part by which the grinding is effected; and different shapes and thicknesses are prepared to suit different kinds of work. The workman holds the glass decanter or other article against the edge of a wheel, and modifies the position and pressure according to the effect desired to be produced. The iron wheels, wetted with sand and water, are used for grinding away the substance of the glass; the stone wheels, with clean water, for smoothing the scratched surfaces; and the wooden wheels, with rotten-stone and putty-powder, for polishing. The *engraving* of flint-glass consists in the production of devices on the surface more delicate than can be produced by the cutting wheel. It is effected by the use of very small discs, generally of copper, and moistened at the edges with emery and oil, and requires great taste and judgment for its due performance. The *parti-coloured* specimens of flint-glass are produced in a remarkable way. The working-tube of the maker is first dipped into a mass of colourless glass, and then into one of coloured; the glass is fashioned and annealed in the ordinary way, and then it is cut by the wheels; and according to the depth of the cutting or grinding, so does the workman penetrate, nearly or quite, through the coloured glass, giving rise to a beautiful play of tints. A different method of obtaining some such effect as this was devised by Mr. Johnson in 1853. It consists in laying a piece of glass on another piece of a different colour; softening and uniting them by the heat of an enamel-furnace; stamping a device on the upper surface by a die; and then grinding away most of the upper glass—by which the upper colour presents itself as a device set or incrusted in the lower. The *incrusted* glass, or *crystallo-ceramie*, invented by Mr. Pellatt, consists in forming a small medallion bas-relief, alto-relief, or other article, of a kind of clay which has the property of expanding and contracting by changes of temperature just in the same degree as flint-glass; this is imbedded in a mass of red-hot glass; and when cooled, annealed, fashioned, ground, and polished, the glass appears with the device in the middle of its substance; the clay, under these circumstances, presenting an appearance almost exactly like that of unburnished silver. The *gilding* of flint-glass is effected by processes not differing much from that of porcelain. [PORCELAIN MANUFACTURE.] Two or three patents have been taken out for *electro-gilding* on glass: but this process has not yet come extensively into use.

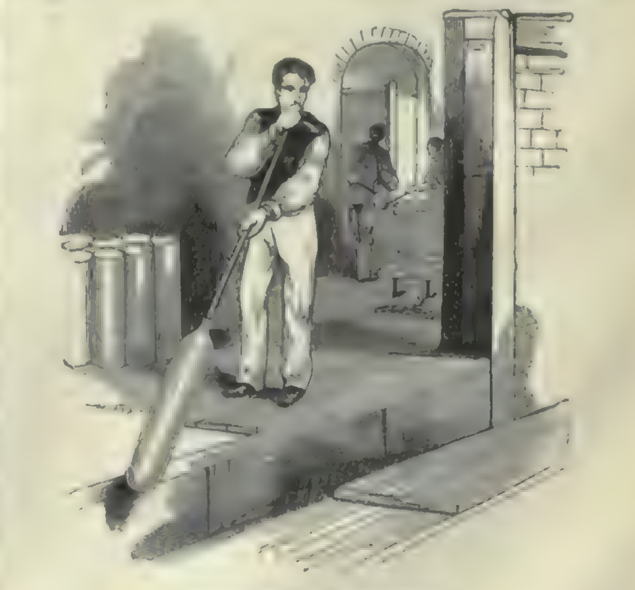
Artificial Gems.—Before passing to the consideration of other kinds of glass, we may say a few words concerning the art of making imitative gems and precious stones, which resemble flint-glass more than any other substance. A transparent, fusible, dense glass, called *paste* or *strass*, is the basis employed. To make good strass is the primary work to be done. There are many recipes for producing it. One, by Loysel, consists in using pure silica, 100 parts; red oxide of lead, 150; calcined potash, 30; calcined borax, 10; and arsenious acid, 10. This mixture produces a glass of great brilliancy, much power of refracting and dispersing light (on which the flashing lustre of gems, whether real or factitious, so much depends), and a specific gravity not far different from that of the diamond; it fuses at a moderate heat, and acquires additional brilliancy when kept heated for two or three days. Diamonds are imitated by this uncoloured strass; and other gems by mixing this strass with colouring agents. For every different factitious gem, there are numerous combinations known; but a few examples will suffice to illustrate the general character of all. *Amethyst:* strass, 100 parts; oxide of manganese, 8; and oxide of cobalt, 2. *Aquamarine:* strass, 4800 parts; glass of antimony, 30; and oxide of cobalt, 1½. *Avanturine:* strass, 500 parts; scales of iron, 100; and protoxide of copper, 50. *Beryl:* nearly the same as for aquamarine, of which beryl is only a variety. *Chrysolite:* strass, 7000 parts; and calcined sesquioxide of iron, 65. *Carnelian*, or *Cornelian*; strass, 7000 parts; glass of antimony, 3500; calcined peroxide of iron, 875; and binoxide of manganese, 75. *Emerald:* strass, 7000 parts; carbonate of copper, 65; and glass of antimony, 7. *Garnet:* strass, 1200 parts; glass of antimony, 580; purple of cassius, 3; and binoxide of manganese, 3. *Lapis lazuli:* strass, 7000 parts; calcined bones, 570; oxide of cobalt, 24; and oxide of manganese, 24. The golden veins in this beautiful stone are imitated by painting in the composition with a mixture of gold-powder, borax, and gum-water, and then applying a gentle heat till the borax fuses. *Opal:* strass, 960 parts; and calcined bones, 48. *Ruby:* strass, 45 parts; and binoxide of manganese, 1; or in another variety, 1 part of topaz paste, which has turned out too opaque, with 8 of strass, fused together for thirty hours, cooled, and fused again in small pieces before the blowpipe. *Sapphire:* strass, 3600 parts; oxide of cobalt, 50; and oxide of manganese, 11. *Topaz:* strass, 1050 parts; glass of antimony, 44; and purple of cassius, 1. *Turquoise:* blue strass, 20 parts; and calcined bones, 1. There is a peculiar mode of producing imitative rubies and emeralds by the use of a kind of alum-glass, subjected to a long and elaborate series of processes; and another, by M. Gaudin, for producing imitative sapphires by an equally elaborate treatment of alum and sulphate of potash. There are other modes of imitating gems; but we need not notice them here.

Crown Glass.—This is one of two varieties of *blown* glass. It is made without any admixture of metallic oxide, and is both specifically lighter and much harder than flint-glass. Many receipts have been given for the production of this kind of glass. At the great works of St. Gobain, in France, the mixture of ingredients is said to be: fine white sand, 100 parts; carbonate of lime, 12; carbonate of soda, calcined, 48; clippings of crown-glass, 100; with minute portions of manganese and cobalt to correct impurities, and to remove the colour which those impurities would impart; they are not therefore at all times necessary. In England the ingredients are mostly sand, alkali, and slaked lime, in the proportions of 200 of the first, 330 of the second, and 15 of lime, to which is added about half the weight of the three materials in broken crown-glass, called by the makers *cullet*. The perfect fusion and refining of these materials are usually accomplished in about forty hours. Crown-glass is made by blowing, in the form of circular plates of 54 to 70 inches diameter. A quantity of glass in the pasty state is collected upon the end of a hollow iron tube, five feet long, similar to the tube used for blowing flint-glass. The lump of glass is then converted, by blowing through the tube, into a hollow globe of the requisite substance. This globe is flattened at the side opposite to the tube by pressing it upon a hard plane surface; a solid rod of iron having a small quantity of melted glass at the end is applied, and adheres to the centre of the flattened side opposite to the tube; the tube is finally removed by wetting the glass near the point of union, leaving a small circular hole. To arrive at this stage the glass must have been several times re-heated, by placing it, when connected with the tube, within a small opening left for the purpose in the wall of the furnace. When transferred from the tube to the solid rod, called a *pontil*, it must be again heated in the same manner, and is then twirled round by the workman somewhat in the manner that a mop is twirled to drive off the moisture; with this twirling the softened material is continually driven off from the centre by the centrifugal force; the hole just mentioned expands, from a few inches to a foot or more in diameter, when suddenly, and in a most unaccountable manner, it flies open, and the whole substance is converted into a flat disc of circular form, and, except at the centre, where it is attached to the rod, of a uniform thickness. This *flashing* of the glass as it is called, is one of the most striking and surprising things in the whole manufacture. The centre parts are used for the commonest purposes, such as glazing outhouses and the poorer kinds of windows. As the shape of the tables or pieces of glass is circular, and as there is a bulb or bull's eye in the middle, it is impossible to obtain very large panes of crown-glass; and the differences of quality are so great and so uncertain, that the best are worth thrice as much per square foot as the worst. Nevertheless, there is always a brilliancy of surface upon crown-glass, which renders it valuable.



Flashing-out Crown-glass.

Sheet Glass.—This is another kind of blown-glass, which has become a very important article of manufacture in England within the last twenty years. Before that time, glass of a peculiar kind was imported, under the names of *broad*, *spread*, or *German sheet-glass;* but the sheet-glass of modern make is a French invention, and French workmen are largely employed in its manufacture, even in English establishments. It required six years, 1832 to 1838, for Messrs. Chance and other manufacturers to overcome the numerous difficulties which beset



Swinging and blowing Sheet-glass.

the manufacture; the difficulties were at length mastered; and among other results, "Crystal Palaces" were rendered possible. The process of making is from first to last very remarkable. The workman gathers up a quantity of the semi-molten glass on the end of a tube; rolls it on a concave block of wood to give it a cylindrical form; and then swings it completely round in a vertical circle, blowing through the tube repeatedly. A recess is formed in the floor of the building, to afford room for this swinging. Much bodily strength and great nicety are required in this operation. The hollow cylinder of glass stretches out by the swinging; but it must be so skilfully managed that the stretching may occur equally in every part, bringing the glass to one uniform thickness. The rotating before a fire, the blowing, and the swinging, are repeated until the proper thickness is attained, and the cylinder has attained the length of four, five, or even six feet. By a mode of causing the heated air within the cylinder to expand, the remote end becomes burst open; the tube is detached, and then the other end is expanded also. The cylinder, symmetrically shaped from end to end, is then laid down; and a diamond, fixed to the end of a long handle, is drawn along the interior, making a cut. The cylinder is placed in an oven, with the cut or fissure uppermost; it gradually opens, and flattens down to a sheet on a very smooth surface. The sheet is rubbed smoothly and evenly with a piece of charred wood, until as free as possible from any irregularities; after which it is annealed in another oven. Such sheets, when first made in England, seldom exceeded 36 by 20 inches; but the usual size now is 47 by 22 inches; and some rare examples have been produced as much as 77 inches in length, requiring no less than 38 lbs. of glass to be taken up on the end of the tube. Although sheet-glass, thus made, is less brilliant and more undulating than crown, its available size is so much larger, that its use has in recent years become very extensive. It was with sheet-glass that Messrs. Chance glazed the Crystal Palace in Hyde Park in 1851; the glass was made in sheets 49 inches by 30, from cylinders more than 4 feet long by nearly 10 inches in diameter: each sheet was cut up into three panes, 49 inches by 10; and of these there were 300,000 in number, measuring 1,000,000 square feet, and weighing 400 tons. The Crystal Palace at Sydenham has since been glazed with the same kind of glass. Messrs. Chance have recently succeeded in devising a process for grinding and polishing sheet-glass, by which it acquires nearly all the beauty of plate-glass with a much less weight; it is much prized by photographers. The German, or broad-glass, above adverted to, is made by the cylinder process, like sheet-glass; but it is clumsily-fashioned, the cylinder is cut open by scissors, and is made to spread out on a layer of sand in the oven, which does not admit of the production of so much smoothness and regularity. Until 1836 the cylinders of sheet-glass were cut open by a piece of red-hot iron; but now a diamond is employed. Such of the Bohemian and Venetian decorated glass as does not belong to the flint-glass kind, is made by the cylinder process.

Plate Glass.—This is both blown and cast. The first-named process was alone employed in England until the year 1773, when cast-plate began to be made. Larger pieces can be made by this than by any other method. The manufacture is difficult and costly. The ingredients are chosen with the greatest care, and every possible amount of skill is brought to bear on the manufacture. The ingredients used are sand of the purest and whitest quality, and soda produced by the decomposition of common salt and lime: manganese and oxide of cobalt being added for the purpose of discharging colour. Soda is preferred to potash or pearl-ash because the glass that is made with it flows better when in fusion, a quality of much importance where large quantities are employed for the production of the same piece. The lime acts as a flux, and is used in proportions varying from 1-24th to 1-16th of the whole materials employed. Besides these ingredients, it is necessary to use a large proportion of broken plate-glass or cullet. The following is one among many scales of ingredients: Lynn sand, well washed and dried, 720 parts; alkaline salt, containing 40 per cent. of soda, 450; lime, slaked and sifted, 80; nitre, 25; broken plate-glass, 425. It requires 40 hours' exposure to the full heat of the furnace to reduce the materials to the proper state of fusion and vitrification. When this is accomplished, the glass is transferred from the melting-pot, by means of copper ladles, to a large vessel called a *cuvette*, previously heated to a very high degree; when filled, it remains some hours in the furnace, to disperse the air that may have been introduced into the mass by the operation of ladling. When this effect has been produced, the cuvette is withdrawn from the furnace and taken to the casting-table, over the upper end of which it is raised and suspended by means of a crane. It is then thrown into an inclined position, by which the contents are allowed to flow out upon the table. The liquid glass is distributed by means of a roller over the whole surface of the table, bars of metal being placed at each side along its entire length, and across the bottom, in order to prevent the glass from running upon the floor. The casting of large plates of glass is one of the most beautiful processes in the arts: the large mass of melted glass, rendered in a high degree luminous by heat, exhibiting changing colours in the sheet after the roller has been passed over it. Previous to the casting, the table is placed with one end against the mouth of an annealing oven; and as soon as the plate is set, it is carefully slipped from the surface of the table to the floor of the annealing oven. When the oven has received as many plates as it will contain upon its floor, the door is closed and its crevices are stopped with mortar or clay, to insure the gradual cooling of the plates. The plates remain in the oven during a fortnight, after which the ovens are opened and their contents are withdrawn. The plates are then squared by means of a glazier's diamond, then ground and polished, and when intended for mirrors they are silvered. In order to their being ground they are imbedded in plaster of Paris. To commence the grinding, powdered flint is rubbed steadily and evenly over the surface by machinery worked by steam power, the two sides of the plate being ground in succession. Emery powder is then substituted for ground flint, coarse at first, but finer afterwards, as the rougher inequalities of the surfaces are removed. The polishing is also performed by steam-machinery. The plates are firmly fixed upon large tables, and the polishing instruments, which are of wood covered with many folds of woollen cloth, having carded wool between each fold, are passed to and fro over the surface. The polishing substance used is colcothal, and oxide of iron which remains in the retorts after the distillation of acid from sulphate of iron; the two surfaces are polished in succession.

The novelties introduced within the last few years in the plate-glass manufacture are as numerous as those which bear relation to sheet-glass; they have had the effect of cheapening the price and increasing the attainable size of the plates. Messrs. Swinburne, a leading firm in the glass trade, have it recorded in their books that their charge, in 1771, for a plate measuring 50 inches by 40, was 61*l*. 3*s*., whereas the price in 1856 was 4*l*. 4*s*. Some of the recent inventions relate to the form of the furnace and melting pots; some to the mode of tilting over the molten metal; some to the form and construction of the casting-table; and some to the mode of effecting the difficult operation of transferring the plate of glass from the table to the annealing oven. A few years ago Messrs. Hawks & Crawshay made for Messrs. Swinburne a casting-table of extraordinary size; it was a solid mass of iron 18 feet 4 inches long, 10 feet 10 inches wide, and 7½ inches thick, weighing 26 tons. A planing-machine was expressly constructed for planing and smoothing this iron surface. When the large plates of glass are annealed, the grinding and polishing begin: these processes, like all else, have been recently made the subjects of much inventive skill; but their details need not be noticed here. It is an interesting fact, connected with the history of the plate-glass manufacture, that the machinery constructed by James Watt for the Company in 1788 was still in existence, at the Ravenhead Works, and even in use, in 1858.

Bottle Glass.—This is the commonest kind manufactured, the alkali employed being the cheapest that can be procured, with the addition of a portion of lime to assist fusion. Considerable manufactures of bottle-glass are carried on at Newcastle-upon-Tyne, encouraged by the low price of the fuel (small coal) which is used in the furnaces. The ingredients are usually nothing more than lime and sea-sand, the latter article having been frequently wetted with sea-water, and allowed to dry, in order that the salt may be allowed to deposit itself in the sand; the soda contained in the salt is the only alkali, properly so called, that is used. Or, another mixture is, Tyne-sand, lime, and the refuse of the soap and alkali works. Bottle-glass is fashioned by blowing, much in the same manner as flint-glass, but with the addition of a moulding process. The description given in a former paragraph of making a flint-glass perfumery bottle will suffice to convey a notion of the mode of making wine and beer bottles, pickle and oil bottles, &c.; except that the latter are made with much less nicety. Four men can make about a hundred beer bottles in an hour. There is a greater weight of coarse green bottle-glass made in England every year than of all other kinds of glass combined.

Bottle-glass makin.

Stained or Coloured Glass.—Coloured glass is more easily produced than colourless, seeing that many niceties in the choice and management of ingredients are necessary to remove all tint from the glass. Nevertheless, to produce a particular colour is an art requiring much skill. As in the instances of enamels and artificial gems, the colours are mostly produced by adding metallic oxides or chlorides to the ingredients for the glass. Sometimes these are put into the melting-pot, to make the glass equally coloured throughout its substance; sometimes a coloured layer is applied to a colourless substratum. An example of this last-named kind has been noticed in a former paragraph, concerning cut flint-glass vessels exhibiting a gradation of tints; and flat panes of glass are produced in an analogous way, by collecting colourless glass on the end of a tube, dipping it into coloured glass, and then flashing it out into crown or sheet glass. So far as concerns the actual manufacture of coloured glass, the ingredients are nearly or quite the same, whether it be surface-colour or through-colour. What is called stained or, more properly, painted glass, however, is generally understood to be something in which the artist is more concerned than the manufacturer. It is a kind of enamel painting, or enamelling, and is effected in the way described in the next article. [GLASS PAINTING.]

Soluble or Water Glass.—We may here add a few words concerning soluble glass, which is at present exciting some attention. It is a chemical agent rather than a manufactured product; still, it is a vitreous substance as soon as it has solidified. About the year 1825, Dr. Johann Fuchs, of Nürnberg, commenced a course of experiments on the production of a liquid glass, produced by a fusion of silica with potash and soda. From time to time the subject came under public notice, but not with any definite result until recently. In the spring of 1859, at the request of the Prince Consort, Dr. Fuchs gave a summary of all that he had done, in a paper read before the Society of Arts. He made many varieties of the liquid glass, some with soda, some with potash, and some with both alkalies, combined in a particular way with crushed quartz or quartzose sand. He had been struck with the possible value of these silicates as a varnish, which, hardening into a glass, would preserve the surface of stone from decay; but his chief labours were towards the production of a new vehicle for fresco-painting. Meanwhile, Professor Kuhlmann, of Lille, had been engaged for many years in studying the action of the soluble silicates with the salts of lime; and in 1857 he made known the results of his method of proceeding, in producing a stone-protecting silicate. An English experimentalist, too, Mr. Ransome, was working towards the same end, but by a different path. He devised a mode of making artificial stone, by combining sandy or stony fragments with silicate of soda; and he also produced a vitreous varnish for the surface of stone, consisting of silicate of calcium instead of silicate of soda. Portions of the Louvre, of the Cathedral of Notre Dame at Paris, of the Houses of Parliament at Westminster, of the Baptist Chapel in Bloomsbury Street, of the Pavilion at Brighton, of the Custom House at Greenock, and of other buildings, have been coated with one or other of the different kinds of water-glass; but many controversies have thence arisen, and it remains yet to be proved how far this kind of vitreous coating will be permanently protective. The causes which bring about that decay of stone implied in all these experiments, are noticed under ATMOSPHERIC INFLUENCE. Another kind of soluble glass, intended to protect woodwork from the action of fire, is noticed under FIREPROOFING.

Glass Trade. The glass-trade in its fiscal and commercial relations, presents many instructive features. At an early period of its history in this country the glass manufacture became an object of taxation, and duties were imposed by the 6 and 7 William and Mary, which acted so injuriously, that in the second year after the act was passed one half of the duties was taken off, and in the following year the whole was repealed. In 1746, when the manufacture had taken firmer root, an excise duty was again imposed, at the rate of one penny per pound on the materials used for making crown, plate, and flint-glass, and of one farthing per pound on those used for making bottles. In 1778 these rates were increased 50 per cent. upon crown and bottle-glass, and were doubled on flint and plate glass. The rates were further advanced from time to time in common with the duties upon most other objects of taxation, and in 1806 stood as follows:—on plate and flint-glass, 49*s.* per cwt.; on crown and German sheet-glass, 36*s.* 9*d.* per cwt.; on broad glass, 12*s.* 3*d.*; and on common bottle-glass, 4*s.* 1*d.* per cwt. In 1813, those rates were doubled, and with the exception of a modification in 1819 in favour of plate-glass, then reduced to 3*l.* per cwt., were continued at that high rate until 1825. In that year a change was made in the mode of taking the duty on flint-glass, by charging it on the weight of the fluxed materials instead of on the articles when made, a regulation which did not affect the rate of charge. In 1830, the rate on bottles was reduced from 8*s.* 2*d.* to 7*s.* per cwt. The next alteration made in these duties occurred in 1835, when, in consequence of a recommendation contained in the thirteenth Report of the Commissioners of Excise Inquiry, the rate upon flint-glass was reduced two-thirds, leaving it at 2*d.* per pound; a measure rendered necessary by the encouragement given under the high duty to the illicit manufacture, which was carried on to such an extent as to oblige several regular manufacturers to relinquish the prosecution of their business. Such were the variations in the rate of duty; and the amount of revenue was equally fluctuating. In 1793, when taxation was comparatively low, the quantity of all kinds of glass made and retained for use in the kingdom was 407,203 cwt., and the amount of revenue obtained from it 177,408*l.* The average rate of duty was therefore 8*s.* 8½*d.* per cwt. upon the whole quantity. In 1834, the rate of duty had by progressive additions become fourfold what it was in 1793, the average being 35*s.* 7½*d.* per cwt. upon the aggregate quantity used; and although the population had in the mean time increased more than 60 per cent., the quantity of glass which was taken for use was only 374,351 cwt., or one-twelfth less than was so taken in 1793. If the quantity used in proportion to the population had continued the same, that quantity would in 1834 have amounted to 663,740 cwt., and a revenue equal to what was realised would have resulted from an average rate of 20*s.* instead of 35*s.* 7½*d.*

It was in 1845 that Sir Robert Peel took off the duty on glass. The effect was very marked—not so much on account of the actual duty thrown off, as on the removal of the exciseman from the glass-works, where he had hampered the manufacturer in all experimental attempts to improve the quality and cheapen the price of the manufactured article. Immediately before the removal of the duty, there were fourteen manufacturers of crown and sheet-glass in the United Kingdom; they became at once overwhelmed with work. The makers had neither buildings nor hands enough; they built new works, and hired workmen from abroad. The Frenchmen who worked at crown glass making could command 5*l.* a-week; while the makers of sheet glass earned 4*l.* to 8*l.* a-week. New companies were formed, and capital was thrown into the glass trade from various quarters. As in many similar cases, however, incompetence and recklessness did their work; the trade was weeded in the course of a few years, and the manufacture (of crown, sheet, and plate) is now in the hands of a small number of very large establishments. The excitement in England had a remarkable effect in Belgium. In the glass factories of that country, the workmen are engaged, not for a definite period, but for the "life of the furnace," as it is called, that is, as long as the furnace remains heated. The manufacturers, at the period in question, maintained the "life" of their furnaces as long as possible, to prevent their workmen from migrating to England, or from demanding higher wages. All these matters gradually found their proper level; and the glass trade is now extensive and steady in England, without being disturbed by convulsive changes.

The glass-trade, as far as concerns exports and imports, is not one of distinguished magnitude. The English factories are able to supply most of the home demand; while they are not well able to command a large export trade.

GLASS-PAINTING. The terms Painted Glass and Stained Glass are often used, and even by writers on glass-painting, as though they were synonymous. But there is a broad distinction between the two. Stained glass, is glass the substance of which has been stained or coloured in the process of manufacture. [GLASS MANUFACTURE.] Painted glass, is glass which, whether previously stained or colourless has had a design painted upon it with colours, usually metallic oxides, combined with a vitreous vehicle, or flux; and which colours, on being subjected to a powerful heat, have become permanently united with the surface of the glass. Windows formed wholly of one or other of these kinds of glass would be strictly either stained or painted glass windows, as the case might be. In mediæval examples, however, what are called painted glass windows are usually formed of a combination of stained and painted glass.

The art of making coloured glass was known to the Egyptians and Assyrians, and from them passed to the Greeks and Romans. That glass was used for windows by the Romans is certain from more than one passage in Latin authors, and from specimens of window-glass having been found both at Pompeii and Herculaneum. It is not known, however, though it is not improbable, that they glazed their windows with stained glass; but stained glass windows must have been in use at a comparatively early period in Byzantium. Byzantine-Greeks appear also to have been the first practitioners of painting on glass; and it is conjectured, with reason, that the practice of glazing with coloured glass in ornamental patterns, and the art of painting on glass, were both introduced into Western Europe from Byzantium, by way of Venice and Marseilles. The practice of glazing windows with stained glass arranged in patterns was imitated from the Byzantine-Greeks by the Saracenic races, and has been continued in the cities of the East down to the present time. The earliest reference to the use of stained glass windows in Europe appears to be in a passage of Prudentius (quoted by Labarte, 'Handbook of the Arts of the Middle Ages,' p. 66) about the beginning of the 5th century; but a more distinct mention of them is made in the following century. Painted glass windows are not spoken of for two or three centuries later.

The earliest existing examples of painted glass windows which Lasteyrie has been able to discover are in the abbey of Tegernsee, in Bavaria: they were presented to the abbey by Count Arnold in the year 999. Five other windows in the same abbey, painted by the monk Wernher, date between 1068–91. At Hildesheim there are also some which are attributed to one Bruno, and to the years 1029–39.

The earliest examples in France, the country in which the art of glass-painting was, during its most flourishing period, practised with the greatest success, belong to the 12th century: the oldest being a representation of the Funeral of the Virgin, in Angers Cathedral, of the first half of the century; the others are some medallion windows of a very remarkable character, placed in St. Denis by the Abbé Suger in the latter half of the century.

It was in the latter part of the 12th and the 13th centuries that the art made its greatest advance. Painted glass windows had now come to be regarded as essential in religious edifices of any pretension. It was the period in Gothic architecture corresponding to our Transition, and First Pointed or Early English styles. Thirteenth century painted glass windows abound in France, and are not unfrequent in Germany and our own country. They are of the kind known as mosaic and medallion windows; that is, the ground is made up of small pieces of stained glass of the shapes and colours requisite to form the patterns, while, as it were, imbedded in the midst of the mosaic ground, are medallions of a circular, trefoil, or quatrefoil shape, on which subjects from Scripture or the lives of the saints, are painted. The ground is usually of a rich ruby or sapphire hue; and a border of a playful and often an extremely graceful design incloses the whole. The figures are necessarily small, and, as in all the painting of that time, are drawn without much artistic skill. In these early examples, the drawing of the faces, hands, &c., is expressed by little more than a sort of outlining with a bistre or other dark colour. Shading, properly so called, and half-tints, are not attempted. The colour of the glass is preserved, for the most part, unbroken. But the subjects are treated with much quiet religious feeling, simplicity, and purity, while the colours are very rich and finely harmonised. Indeed, as decorative works, the windows of the 13th century are superior to those of any other period. The oldest English examples are in Canterbury and Salisbury cathedrals; but the finest are the magnificent five sister lancets (50 feet high) of York Minster, and the great rose window of Lincoln Cathedral, in which the central Majesty (or Christ in Glory) is surrounded by sixteen compartments containing the typical events of the life of Christ. The chief French examples—many of them of extraordinary grandeur and beauty—are in the cathedrals of Chartres, Bourges, Paris, Amiens, Soisson, Rouen, and Sens, and the Sainte Chapelle, Paris.

The painted glass of the 14th century (the epoch of our Second Pointed or Decorated Gothic style) was more vivid in colour, broader in style, and the painting better executed than in that of the preceding century; but it was less pure in conception, and less strictly subordinated to the general architectural effect. The mosaic ground is no longer universal; rich red or blue damasked stuffs or diapering being often substituted; and, instead of small Scriptural subjects in medallions, we find a prevalence of single figures under large heavy canopies, each occupying a single light (of the kind known as canopied windows, first introduced in the latter part of the 13th century); heraldic bearings are also now largely introduced; foliated ornaments and geometrical patterns abound, but the trefoil so common in the preceding style is seldom, if ever, seen in this; and, instead of the graceful arabesque border, we find frequently a running pattern of vine-leaves and grapes. Grisailles, or subjects painted in gray, now first came into vogue. One of the best examples of English work of this period is the east window of Bristol Cathedral: other characteristic examples occur at York Minster; Exeter Cathedral; the chapel of Merton College, Oxford; Tewkesbury Abbey Church; Norbury Church, Derbyshire; Lowick Church, Northamptonshire; and several other parish churches. Characteristic French examples occur in the cathedrals of Chartres, Evreux, Beauvais, Limoges, Lyon, Strasbourg, and Narbonne.

In the 15th century (the period of our Third Pointed or Perpendicular Gothic) a great change took place in glass-painting. The windows became still more individualised and less dependent on the architecture. The subjects occupied a larger space, and were treated more as pictures. Either each filled a distinct panel, or they were placed one above another without any ground to separate them. The mosaic pattern-work of stained glass was now altogether discarded, the whole being painted. The details are usually put in with much care, and very skilful manipulation is exhibited throughout. But the colour is poor, white glass is chiefly employed, and the general effect is cold and comparatively feeble. Some of the examples—the earlier ones especially—are, however, very elaborate and impressive: of this class is the magnificent east window of the choir of York Minster, which consists of no fewer than 116 compartments, each having a separate subject. This is undoubtedly the finest example of the style in England; and Lastruvie says it is one of the very finest in Europe. It was during this period that buildings and landscapes began to be freely introduced as backgrounds to the compositions. Canopied windows of this date have the canopies of a very ponderous character. Chichester and Winchester cathedrals; Henry VII.'s Chapel; Lincoln College Chapel, Oxford; Cirencester Church; Barton Church; Ludlow Church, Shropshire; and many other parish churches, possess excellent specimens of the painted glass of this period. Of French work, very fine examples are found in the cathedrals of Bourges, Evreux, Aix, Mans, &c. In Italy, where painting on glass had not hitherto been practised with much success, many works of great ability, though in a pictorial style, were now executed; and the names are preserved of many eminent artists who painted on glass, including several distinguished painters in oil and fresco. The artists of Florence particularly excelled as glass-painters.

By the end of the 15th century Gothic architecture was everywhere dead or dying; and the old mediæval spirit had departed also from the painting of glass. Palatial and domestic buildings were now adorned with painted glass windows as well as ecclesiastical edifices. The aim of glass painters was to rival the effects of oil paintings. Windows were indeed often mere imitations of oil pictures. The works of Raffaelle, Giulio Romano, Albert Durer, and other distinguished painters, were either copied or imitated. Subjects in which were a multitude of personages arranged with all the elaborate artifices of pictorial composition; landscapes with the effects of aerial, and buildings showing complex linear, perspective; foreshortened figures; the depth and obscurity of chiaroscuro,—all were attempted to be exhibited in painted windows, and the result was that what would have been impressive on a wall or canvas, looked on glass a shallow and feeble transparency. We have in this country some of the least unsatisfactory, because among the earliest and transitionary examples, in the splendid series of twenty-seven large windows of King's College Chapel, Cambridge (painted in 1527 and succeeding years). But in them is seen how entirely the true character of window painting was now lost sight of. The glass is treated as though it were canvas or panel, the picture being carried over the entire surface, without any regard being paid even to the massive stone mullions which occasionally cut the compositions in the most awkward manner. Another very superior example of its class is the great east window of St. Margaret's, Westminster. The celebrated windows of Fairford church also belong to this date; they are usually ascribed to Albert Durer, but no doubt inaccurately, though they are of German or Flemish execution. In France there are numerous fine examples of 16th century windows in the cathedrals of Bourges, Auxerre, Auch, Beauvais, Sens, Rheims, &c.; in St. Ouen, at Rouen; St. Gervais, Paris; and the Sainte Chapelle, Versailles. The cathedrals of Germany and the Netherlands afford many fine examples of this period, treated, as are those of Italy and France, quite in the spirit and much in the manner of the contemporaneous painting in oil. In many instances, indeed, the brilliant colours of glass were altogether neglected, the picture being a dingy monochrome. Several specimens, mostly of small size, of the German, Flemish, and Swiss painted glass of this period are in the South Kensington Museum.

From this time glass painting fell more and more into disrepute; though windows continued to be painted, and some glass painters, especially in France, acquired a certain celebrity. But the works produced up to some time in the present century continued to be copies of oil paintings, or of designs which could only be effective if painted in oil. What these were in our own country, even when artists of the highest standing were commissioned to prepare the designs, may be seen in the windows of New College Chapel, Oxford, designed by Sir Joshua Reynolds and painted by Jarvis; and of Trinity College Library, Cambridge, designed by Cipriani.

The renovation of the art was coincident with the revival of Gothic architecture. It has since been studied earnestly by archæologists, and pursued zealously by a numerous body of practitioners (aided by the experiments of many eminent chemists) in England, France, and Germany; and great success has been attained in the preparation of the glass, and in the various technical and manipulative processes. Hitherto, however, little original power has been exhibited in the designs; the object aimed at being mainly to produce faithful imitations of mediæval glass, the style selected being that of the 13th, 14th, or 15th century, according to the taste of the artist or the desire of the patron.

We have now to describe very briefly the method of painting on glass. Obviously this can only be done generally. The art can only be learnt from a practitioner, and of processes so strictly technical even a description would be out of place here. We shall at the end of the article give references to technical treatises, where the several processes are explained at length, and the various materials employed are fully described.

The first step is to prepare a careful cartoon the size of the painting. For a small work on a single plate of glass, the glass is laid on the cartoon, or on a tracing made from it, and the outline is accurately traced on the glass with black or brown, composed of a very fusible vitreous flux, coloured with a metallic oxide, and ground extremely fine in an essential oil (tar, spike, or lavender). The parts intended to be yellow, orange, or red are then coated, either on one or both sides, according to the tint required, with a mixture composed of an alloy of silver and antimony ground up with the red oxide which is obtained by subjecting sulphate of iron to a red heat. The glass is then exposed in a furnace or muffle to a red heat, or, as it is termed, fired, in which process the tracing colour is fused, and adheres permanently to the glass. The mixture of silver and antimony stains the glass, but does not melt, so that the oxide of iron, which is in the state of dry powder, may be brushed off, leaving the glass coloured, but as transparent as before. The other colours, composed of a very fusible glass coloured with metallic oxides, are then added, and the glass is again fired. In most cases the glass is fired between the application of each colour, as some colours require more heat than others. In the Munich works the glass is often fired seven times.

For convenience we have described the process as followed on a single sheet of glass; but in fact painted windows are usually composed of many pieces of glass fixed together in a leaden frame-work. For a painted window of this kind, the first step is to arrange carefully from the cartoon the several compartments into which the work shall be divided; and to determine the sizes and shapes of the pieces of glass, and the direction of the lead-work, so as not to interfere with, but if possible to support, the outlines of the figures and the lines of the composition, whilst sufficient firmness is preserved to the window itself. In a window of this kind, it will be remembered, the artist does not paint upon white glass merely, but as far as possible avails himself of glass already coloured (pot-metal as it is technically termed), only in his subsequent processes modifying by shadows or superficial tints the original colours. Each piece of glass is separately painted, shaded, or diapered, and then fired; the laying on of the colours and the firing being repeated as often as necessary. When the painting is completed the pieces are fixed in their leaden frame-work; this is supported by an arming of iron saddle-bars, and the whole is placed in its proper position in the building.

In glass painting the artist has many difficulties to surmount; and he can only hope to surmount them by a clear comprehension of the special requirements of his art, and the adoption of a specific style of treatment. His work is so placed usually that it can only be looked at from a distance. Being a window, his painting must not obscure but only modify the light. He may graduate his tints, but, when in position, not only do his more delicate gradations disappear, but even the half-tints are lost. In the countenances, refinements of expression are commonly valueless. The transparency of the medium at once refutes any close imitation of solidity in the objects. Hence the attempts to copy pictorial effects are always unsatisfactory. There is little chance of success except by unreservedly accepting the conventionalities of the art, and treating the window as a window, and not as a portion of wall-surface. The subject must be conventionally rendered, but not necessarily, therefore, archaically; there is no reason why the forms, costumes, and composition should not be as perfect as the artist can make them. In the colouring of the parts as well as of the whole, the most gem-like richness and brilliancy must be aimed after; and the window be rendered at once harmonious in itself, and in harmony with the other windows, as well as with the building of which it is a portion.

The following works may be consulted on the history of painting on glass: they will supply any further references the student may require. Lasteyrie, 'Histoire de la Peinture sur Verre d'apres des Monumens en France,' 2 vols. fol., Paris, 1838–56, a very splendid and erudite work, in which representations in chromo-lithography are given of the best French examples from the 12th to the 18th century. With it may be compared a 'History of Stained Glass from the earliest period of the art to the present time,' by W. Warrington, 1 vol. fol., 1848, which in a measure does for English glass painting what the work of M. Lasteyrie does for that of France; but unfortunately the series of chromo-lithographic designs (illustrating the changes of style from the 12th to the 16th century) are not copies of old windows, but of windows painted by the author himself in imitation of old ones: many ancient English as well as German and Flemish examples, however, are supplied in Weale's 'Divers Works of Early Masters in Christian Decoration,' 2 vols. folio., 1846–7. In Mr. J. D. Waring's 'Arts connected with Architecture, &c.,' fol. 1858, is given a series of examples executed in coloured lithography, by Mr. V. Brooks, of stained glass windows in Central Italy, from the 13th to the 15th century. Gessert, 'Geschichte der Glasmalerei in Deutschland, und Niederlanden, Frankreich, England, der Schweitz, Italien, und Spanien, von ihrem Ursprung bisauf die neueste Zeit,' 8vo., Stuttgart, 1839. On the theory and practice of the art, see 'An Enquiry into the Difference of Style observable in Ancient Glass Painting, especially in England, with Hints on Glass Painting, by an Amateur' (Chas. Winston), 2 vols. 8vo., Oxford, 1847; and 'An Introduction to the Study of Painted Glass,' by the same author, 8vo., Oxford, 1849; F. W. Oliphant, 'A Plea for Painted Glass,' 8vo., Oxford, 1855; Langloit, 'Essai sur la Peinture sur Verre;' P. Le Vieil, 'L'Art de la Peinture sur Verre et de Vitrie;' G. Bontemps, 'Peinture sur Verre au dixneuvieme siecle,' Par., 1845; E. O. Fromberg, 'Handbuch der Glasmalerei,' Leipz., 1851, translated into English under the title of 'An Essay on the Art of Painting on Glass,' 12mo., 1851; M. A. Gessert, 'Die Kunst auf Glas zu Malen,' translated into English under the title of 'A Rudimentary Treatise on the Art of Painting on Glass,' 12mo., 1851; Sir G. Wilkinson, 'On Colour,' pp. 23–55; and for the ancient Italian method of glass painting, 'Original Treatises dating from the 12th to 18th centuries on the Arts of Painting,' edited by Mrs. Merrifield, vol. i., chap. iv.

There is a kind of ornamental window-glass called *Matted Work*, in which the glass is covered with a very fusible composition, either white or tinted, previously reduced to an impalpable powder. This composition is then removed from certain parts of the glass, according to the required pattern, and, after firing, produces on the glass a dull ground with a bright pattern. The demand for ornamental glass having increased lately, several persons have attempted, some by stencilling, others by the application of machinery, to produce it at a cheap rate; and matted work can now be obtained at one-fourth of the price that would have been charged a few years since.

Another method of ornamenting glass, rather inappropriately termed *embossing*, consists of a bright figure on a dull ground. The parts intended to be dull are painted over with varnish; hydrofluoric acid is then poured on, which etches the glass to a certain depth. After the acid and varnish are washed off, the glass is ground by rubbing with another piece of flat glass and fine emery. This process removes the original surface of the glass, and produces the dull ground; and the design, having been sunken by the action of the acid, is untouched in the grinding process, and left bright.

GLAUBER'S SALT. [SODIUM, *Soda, sulphate of*.]

GLAUCINE, an alkaloid found in the leaves and stems of *Glaucium luteum*. It forms salts with the acids, and has a bitter acrid taste. It occurs in the form of pearly scales. *Glaucopicrine*, found in the same plant, differs from the above compound. The composition of both is doubtful.

GLAUCOMA (from γλαυκός, blue or bluish-gray), a disease of the eye, characterised by the pupil losing its naturally black colour, and presenting a clear or dull greenish hue. It was first described by Brisseau, partly from observations made in the post-mortem examination of the eyes of Bourdelot, physician to Louis XIV. It seems to depend essentially on disease of the choroid membrane and retina [EYE, in NAT. HIST. DIV.], generally combined with morbid alteration in the vitreous humour and hyaloid membrane, and in the lens and its capsule.

The symptoms by which it is indicated are pain in the head, over the brow, or across the forehead, weakness of sight, and a greenish colour of the pupil, most intense when one looks directly down into the bottom of the eye, where it seems almost as if there lay a piece of shining metal. The pupil is rather dilated, and the motions of the iris are slow. As the disease advances, the greenish colour becomes more marked, vision more and more indistinct, and at last, when it is entirely lost, the iris is quite motionless. Frequently the disease spreads to the lens, producing a glaucomatous cataract [CATARACT], and sometimes is accompanied with evident inflammation of the superficial parts of the globe.

The disease seems to consist in chronic inflammation of the deep-seated parts of the eye. Those of a gouty constitution, and especially those who have lived freely, and have passed the middle period of life, as well as persons of scrofulous constitution, or who are employed in very delicate work, are the most frequent subjects of it. It is also more frequent in some countries and classes than others. Scarpa never met with a case of fluidity of the vitreous humour during his long practice at Pavia; while in England such a condition is by no means rare in old persons. Benedict says that he found glaucoma very prevalent among the Jews in Breslau.

On examination of the eyes thus affected, the choroid membrane is found to have lost its black colour from the absence of pigmentum nigrum; it is become dull-brownish, and its vessels are often varicose; the vitreous humour is generally quite fluid, without a trace of hyaloid membrane, of a yellowish hue, or with small brownish-green or green spots scattered through it; the retina is often darker than natural, or marked with reddish or black points; the lens in part of a yellowish or deep amber colour, firm and transparent, sometimes pushed forward, so that the iris is in contact with the cornea.

The only diseases with which glaucoma can easily be confounded are cataract and gutta serena: it may be distinguished by its history; by the greenish colour of the pupil, which evidently arises from changes of structure in the parts behind it, and which is not visible when viewed laterally; by the defect of vision being disproportionate to the change of colour of the pupil; and by the sight being best in a strong light.

Early treatment is necessary, and it should be actively antiphlogistic; blood should be drawn from the temples, and purgatives, mercury, and abstemiousness be ordered. These, if they do not put a stop to the disease, will retard its progress, and relieve many of its symptoms, as the headache, &c. If, however, the pupil becomes quite green and the iris motionless, the case may be regarded as hopeless; for there are no means known by which the changes on which these symptoms depend can be removed.

(Beer, *Lehre von den Augenkrankheiten*; Lawrence, *On the Diseases of the Eye*; Mackenzie, *On the Diseases of the Eye*.)

GLAUCOMELANIC ACID ($C_{12}H_2O_6$, HO?), an acid said to be formed when an alkaline solution of ellagic acid is exposed to the air.

GLAUCOPICRINE. [GLAUCINE.]

GLAZING. This name is given to several different processes in the manufacturing arts, each of which calls for a brief notice.

1. *Window Glazing.*—This is the art of fixing glass in the frames of windows, &c. Putty, with which the glass is usually fixed, consists of whiting and linseed oil. As to the mode of cutting the glass, see DIAMOND. The defective state of most skylights, hothouse roofs, &c., shows that the art of glazing them is very imperfectly understood by those who practise it. When a skylight is glazed in the ordinary manner, the laps or horizontal joinings fill with water by capillary attraction whenever it rains, and the wind drives the water into the house. This process goes on as long as the shower lasts. Sometimes vegetable fibres hang down from the laps, and, acting as siphons, draw off the water taken up by them, which then falls into the house, and by its dropping injures tender plants, &c. The retained water also expands in freezing, and fractures the glass.

The following remarks are the result of long practical experience and careful observation. The edges of the glass which are to form the laps should not be cut straight, but circular; this will add to the beauty of the work, and cause the water to run down the centre of the openings, and not act so much on the bars. The cutting of glass in this manner for domes and other ornamental roofs, where the spaces between the bars are not parallel, was formerly difficult to execute, and expensive on account of the waste of glass; but by a contrivance invented a few years ago, this may now be accomplished with ease, expedition, and economy. The laps should be less than a quarter of an inch wide, and wholly filled with a cement composed of putty with a good proportion of lamp-black, which will remain tougher and be more waterproof than white-lead, carbon being much less soluble than carbonate of lead. Some glaziers cement the laps at the time when they are glazed, and leave a space in the centre to allow, as they say, the water that forms inside to run out; but the spaces thus left are large enough to allow of the formation of sufficient ice to break the glass. Cementing is of little use if done when the work is first glazed. After the glazier has left his work as finished, the glass, which is very elastic, springs up enough to leave the included cement loose and inefficient. The elasticity of the glass may be taken advantage of after the side putty is set firm. If the cement is then pressed into the laps and care is taken that they are dry, the action opens the laps, and the re-action of the glass closes them, and holds the cement fast and firm.

The largest glazing operations ever carried on in this country were probably those at the two Crystal Palaces, Hyde Park and Sydenham. At the former there were 17 acres of window-glass in the roof alone, besides that in the windows. The panes or squares mostly measured 49 inches by 10; and they were fitted into no less than 200 *miles* of sash-bars.

2. *Metal-glazing.*—This has nothing to do with the fixing of glass, or the application of a vitreous coating; it is a particular mode of polishing metals, especially cutlery. The *glazers*, so largely employed at Sheffield, are wooden wheels covered with leather, and charged with fine emery, waxed to deaden the cutting action to a proper degree. The larger kinds are built up piecemeal, with six or more sectors having the grain placed radially. Mahogany, walnut, oak, crab-tree, and birch, are the chief kinds of wood employed, mahogany being the best; and the wheels are turned into proper form before the edges are dressed. The emery is applied in the state of a fine powder, moistened with water. Other varieties of polishing wheel are used, nearly like glazers. Buff-wheels are covered with leather in some cases half an inch in thickness, taken from a bull's neck; or sometimes old military belts are used as a substitute. They are coated with *coarse buff* of sand and water for polishing steel; and with *fine buff* of rotten-stone and oil for brass, Britannia metal, horn, ivory, tortoiseshell, &c. Leather glazers are covered with harder leather than buff-wheels; it is usually thick sole-leather; the emery is attached to the surface by means of glue; and such glazers are used for polishing various kinds of steel goods. Leather polishers are wooden wheels covered with soft thin leather, and supplied with crocus, rubbed on dry; they are used likewise for steel goods. The various leather-edged glazers used by cutlers vary from four to twenty inches in diameter, and from a quarter of an inch to four inches in width at the edge. At Sheffield, leather is tanned expressly for many of these kinds of glazers, with a view to the extraction of every particle of grease. Lapidaries employ wooden glazers in smoothing soft and rounded stones; these glazers are made of beech, birch, or mahogany; and emery is applied to their edges in a powdered form, moistened with water. In what way the emery admits of many different modes of treatment is explained under EMERY; while the relation which the process of metal-glazing bears to other operations of Sheffield goods is shown under CUTLERY.

3. *Fictile Glazing.*—In EARTHENWARE and PORCELAIN, descriptions are given of the circumstances under which a vitreous glaze is rendered necessary on the surfaces of articles in baked ware; and on the modes in which the heat of an oven fixes this coating when applied. We shall here speak only of the glaze itself. Most glazes are white, but they can be deepened to any tint by the addition of the same kinds of colouring ingredients as are usually added to enamels. Nearly all glazes contain lead, except when to be applied to articles which would be injured by that metal. A glaze without lead, for chemical vessels and some other articles, is made of Lynn sand 47 parts, potash 38, slaked lime 9, and nitre 4; these are pulverised, brought to the state of a paste or frit by heat, and again pulverised. One among many kinds of glaze for common earthenware consists of white lead 59 parts, ground flints 36, Cornish stone 16, and ground flint-glass 5. A glaze for porcelain consists of felspar 27 parts, borax 18, fine sand 4, nitre 3, soda 3, and Cornish clay 3; the whole being mixed, ground, heated to a frit, again pulverised, and finally treated with a small addition of calcined borax. A glaze for painted stone-ware consists of felspar 26, soda 6, nitre 2, and borax 1; when these have been fritted together, they are added to a mixture of red lead 50, white lead 40, and ground flint 12. All these various kinds of glaze, when prepared, and about to be used, are ground to powder, and mixed with water to a smooth creamy liquid, into which the ware is dipped. In some few cases, the ware is dipped into water, and the glaze sprinkled on it in the form of dry powder. The heat of an oven finishes the operation.

4. There are other processes of glazing in the arts, which consist in little more than the application of a varnish or glaze of white of egg or some similar substance.

GLAZING. [EARTHENWARE; PORCELAIN.]

GLEANING. The practice of gleaning in corn-fields what the reapers of the harvest leave behind is vulgarly supposed to be a legal custom which the "owner or occupier of the field has no right to prohibit, and that the poor who enter a field for this purpose are not guilty of trespass." The act has, however, been decided to be illegal. In the first case in which the question was raised the defendant pleaded that he being a poor, necessitous, and indigent person, entered the plaintiff's close to glean; and in the second the defendant's plea was the same, with the addition that he was an inhabitant legally settled within the parish. The Court held that the claim had no foundation in law, and that, "it was a practice incompatible with the exclusive enjoyment of property, and was productive of vagrancy and many mischievous consequences." (1 H. Bl. Rep.' 51.)

GLEBE LAND, the portion of land belonging to a parish church over and above the tithes. If there be both a rector and a vicar, the glebe land in the occupation of either does not pay tithes, though if in the occupation of a tenant it does. The representatives of a deceased incumbent are entitled to the corn sown by him upon the glebe. Various statutes have from time to time been passed to facilitate the exchange of glebe lands, which are often scattered in small parcels in different parts of the parish. It is doubtful whether a parson may open mines upon his glebe, though he may work any that are open.

GLEE, in music, a vocal composition in three or more parts, any instrumental addition to which is absolutely illegitimate, because pernicious in effect; except in the case of unsteady performers, when the use of a piano-forte, gently touched, is advisable, as an evil of less magnitude than false intonation and broken time. The word is derived from the Anglo-Saxon ᵹlıᵹᵹ (*gligg*), which signifies *music* generally; hence the term *Serious Glee* may possibly not be so gross a solecism as is commonly supposed; though it must also be admitted that the word usually implied cheerfulness; and we are told by Warton that *gleeman* (ᵹlıᵹman), answers to the Latin *joculator*.

The glee is of English growth, though the madrigal seems to have been its parent. The term is confined exclusively to this country, and does not appear to have been employed till towards the latter part of the 17th century; but Dowland, Ford, Ravenscroft, and others, published nearly a hundred years before compositions having all the character of that which subsequently took the name of *Glee*, frequently calling them part-songs, and occasionally applying the term madrigal to them, notwithstanding their deficiency in what chiefly characterises the latter.

Glees are called *serious* or *cheerful*, according to the sentiment of the poetry. The most distinguished authors of this delightful species of music are—(mentioning only those who now are personally beyond the influence of praise or censure)—Arne, Baildon, Callcott, Cooke, Danby, Hayes, Mornington, Nares, Paxton, Spofforth, Stafford Smith, Stevens, and Webbe.

GLIADIN, *Glutin*, a peculiar azotised vegetable matter which exists in small quantity with the gluten of wheat, and to which the adhesive properties of the latter are owing. It may be separated by boiling alcohol, together with a thick fluid oil which is separable by ether. Gliadin is adhesive, insoluble in water, when dried it is hard and translucent like horn; it dissolves in acetic acid and solution of potash. In composition it scarcely differs perceptibly from gluten. It contains in 100 parts,—

Carbon	53·27
Hydrogen	7·17
Nitrogen	15·94
Oxygen and sulphur	23·62
	100·00

GLOBE, the common term for a sphere, but most frequently used to signify the earth itself, or the sphere on which a representation of the earth or heavens is drawn.

GLOBE MAKING. This special department of industry is one in which few hands are employed, for the demand is limited; but it requires considerable tact and experience. Most English globes are hollow pasteboard balls. A wooden or iron mould is first formed, with wires projecting at opposite sides to represent the earth's poles. Several layers of long strips of paper are then pasted one over another on the mould, the *undermost* not being pasted to the wood or iron, but kept down close upon it. These layers may be from four or five to a dozen in number. When dry, this pasteboard envelope is cut in the line of the (future) equator, and is separated from the mould or ball in two hemispheres. These are fastened by nails to the two ends of a piece of wood exactly equal in length to the diameter of the globe; and the edges of the hemispheres are glued together, so as to form a pasteboard sphere. Two wires, projecting from the two ends of the piece of wood, penetrate the pasteboard, and form the termini of the axis of the globe. The pasteboard is then coated, six or more times over, with a composition of whiting, glue, and oil, until a considerable substance has been laid on; each layer being dried before the next is applied. At this stage of the manufacture any irregularity in the rotation of the globe on its axis is remedied, by increasing the thickness or the weight in particular parts. The plaster surface, when made quite smooth, is then marked with lines to represent the circles of latitude and longitude; this is done by women, who use a beam-compass for the purpose. Meanwhile the engraver has been at work, to produce the geographical delineation which is to cover the globe; the whole surface is divided into lens-shaped pieces, like the gores of a balloon, seeing that it is only by such means that the surface can be easily covered without overlapping or vacuities. Two circular pieces cover the arctic and antarctic regions; and the gores extend only to a meeting point within these pieces. The printing is effected on thin but very tough paper. In globes of moderate size, each gore usually represents 30 degrees of longitude, and 133 degrees of latitude. The pieces are pasted, and laid on with great care—the lines marked on the plaster being taken as guides. Much skill is needed to effect the necessary junction of the edges without overlapping. The globe is then coloured, to mark the divisions of land and water, &c., and is next coated with several layers of strong varnish. There is thus a hollow globe of pasteboard, coated with plaster, covered with printed paper, and finished with water-colour and varnish. The graduated meridian rings are made of brass or of iron. The "poling of the meridian," or adjustment to make the globe revolve truly, follows; and then comes the cabinet work of fixing the globe to its frame or stand—an engraved annulus or ring of paper being prepared to cover the representative horizon.

The same principle of manufacture is followed, whether the globes sell at six shillings or fifty guineas a pair. Small German globes are now imported, however, as low as sixpence each; and it is probable that some more rapid method is adopted for their production. Some of the English globes are as much as 36 inches in diameter. Some, of large size, contain not only the ordinary delineation, but also show the geological structure of the earth, atmospheric currents, trade winds, monsoons, ocean currents, isothermal lines, and trade routes. A celestial globe has been made as much as 72 inches in diameter, but with the delineations written or painted instead of engraved. Slate globes are made, for school use, with only the lines of latitude and longitude marked. Some globes are made with the land portions shown in *relief;* these require a process of embossing by stamping. Embossed globes of this kind are made to show approximately the irregularities on the moon's surface. Mr. Adams makes globes of gutta percha, which can be taken to pieces for convenient packing, or for instruction in putting them together again. He has also invented a globe in which the terrestrial and celestial spheres are superimposed one on the other—but to the disadvantage of both. Ziebermayer of Vienna makes globes in which a small terrestrial sphere is inclosed in a glass sphere marked with the constellations, &c., with mechanism for showing the places of the sun and moon among the stars. Globes have sometimes been made of tissue paper, inflated by air to a diameter of ten or twelve feet, and suspended by a string from the ceiling of a school-room or lecture-room. Betts's smaller paper globes are so constructed as to fold up conveniently into a very small space when not in use. Messrs. Goodyear manufacture globes of inflated india-rubber, or silk coated with india-rubber solution. The globes which have been made large enough for persons to enter withinside—such as Guérin's Georama, 30 feet in diameter, and Wyld's Great Globe, 60 feet in diameter—are examples of building rather than of globe-making.

The engraved paper surface of one of Addison's 36 inch globes was made use of by Professor Rigaud, of Cambridge, for determining the relative quantities of land and water on the earth's surface. The paper was selected with especial care; the printing was effected with as little ink as possible; the drying and cutting out were well attended to; and the pieces were weighed in a very delicate balance. Halley and Long had done the same thing with smaller globes long before; but Rigaud's process was in every way more trustworthy. On all globes the Arctic and Antarctic positions are necessarily left very vague; and the professor could only make guess-work of those regions. The result of a very laborious examination was, that if the earth's surface be divided into 1000 equal parts, 266 of these are dry land, and 734 water. The 266 are thus distributed:—Europe and the adjacent islands 16½, Asia 89, Africa 59½, America 85½, Australasian group 15½. In another mode of grouping, the northern hemisphere comprises 197 land and 303 water: the southern hemisphere 69 land and 431 water.

GLOBE OF COMPRESSION, a name given by Belidor to overcharged mines, that is, producing anything over a two lined crater. [MINE.] Such mines have been used by the besiegers of a fortress to destroy the galleries of the counter-mines, and blow the wall of the counterscarp into the ditch. They were first employed by the king of Prussia, in 1762, at the siege of Schweidnitz.

GLOBULAR PROJECTION. We believe this term has been applied to more than one species of map, but particularly to the projection proposed by Lahire, in which the eye is supposed to be distant from the globe represented in whole or part by one half of the chord of an arc of ninety degrees. This projection gives but a small distortion, compared with that of the stereographic projection; it is however very rarely employed, on account of the projections of most of the great circles being ellipses.

GLOBULAR SAILING. [GREAT CIRCLE SAILING.]

GLOBULIN, an albuminous substance contained in the blood-globules, united with *hematin*, the colouring-matter of blood. It is contained, also, in the crystalline humour of the eye. Its aqueous solution coagulates at a higher temperature than that of albumen. It possesses a slightly alkaline re-action, and in other respects greatly resembles albumen. It is composed of,—

Carbon	54·5
Hydrogen	6·9
Nitrogen	16·5
Sulphur	·3
Oxygen	21·8
	100·0

GLOVE (from the Anglo-Saxon *glof*), a cover for the hand. Casaubon asserts, with reference to a passage in Athenæus (xii. 2), that the ancient Greeks and Romans knew of no such covering for the hands; though he shows that they were in use among the Romans in the time of Pliny the younger. The Persians used gloves in cold weather, a circumstance charged against them as a proof of their luxurious habits. Xenophon, 'Cyrop.,' viii. 8, 17.

In England the etymology of the word shows the early use of gloves. With kings, nobles, and prelates in the Middle Ages they were a costly article of dress, and richly decorated, being sometimes, particularly those of bishops, adorned with precious stones.

While the spirit of chivalry lasted, the glove of a lady, worn in the helmet as a favour, was a very honourable token; and much of the wearer's success was supposed to be derived from the virtue of the lady. The practice of wearing a glove as a favour is mentioned by Hall in his 'Chronicle,' in the reign of Henry IV., and frequently among our old dramatic writers. Nares's 'Glossary,' in voce.

At what is called a maiden assize, or when there are no prisoners to be tried, it has from time immemorial been the custom for the high sheriff to present the judges with white gloves. Formerly on an application for the reversal of an outlawry, the defendant was obliged to appear personally in court and present gloves to the judges. Gloves are not worn in the presence of the sovereign.

In former times it appears to have been a general custom during fairs to hang out a glove from the town hall or some other conspicuous place, and it is said that whilst the glove remained suspended, all who visited the fair were privileged from arrest. The taking down of the glove was the signal that the fair was closed. (See instances and authorities collected in 'Notes and Queries,' vols. vii. and viii.)

At the sale of the Earl of Arran's goods, in the month of April, 1759, the gloves given by Henry VIII. to Sir Anthony Denny were sold for 38*l.* 17*s.*; those given by James I. to his son Edward Denny, for 22*l.* 4*s.*; and the mittens given by Queen Elizabeth to Sir Edward Denny's lady, for 25*l.* 4*s.* Gough 'Sepulchr. Mon., i. 185, says, "These may be supposed some of the oldest gloves extant."

To throw the glove by way of challenge to duel is mentioned in Matthew Paris's History, under the year 1245. He calls it *mos Francorum.* Throwing down a glove as a challenge by the royal champion was a part of the coronation ceremony as late as the coronation of George IV.

GLOVE MANUFACTURE. Gloves are made at the present day of a great variety of substances,—kid, lambskin, buck, doe, dog-skin, and other kinds of leather; together with silk, flax, cotton, and wool, and mixtures of two or more of these. Some are known by names which do not denote the materials used, such as Limerick, Berlin, Woodstock, Kendal, Yeovil, &c. "Habits," or habit gloves, are ladies' short gloves; the name being derived from the gloves formerly worn by ladies on horseback, at a time when long gloves were worn with walking dress.

The following observations on the characteristics of the chief kinds of gloves, in a manufacturing point of view, are mostly condensed from Mr. Perkins's useful little volume on the subject. Kid is valuable for gloves in proportion to its elasticity; when it is both elastic and close in texture, it is employed for the best "town made" gloves, which are equal in quality to the best French. Most of the so-called kid gloves sold at a low price are made of lambskin; the leather is always thicker and heavier than real kid. It is only the very best English kid gloves which are equal to the French; and as the latter have a good name in the market, there is much deception practised. Three-fourths of the real kid gloves sold in England as "French," are made in England, of kid skins obtained from France, Italy, and Ireland. Limerick gloves are a peculiar kind of kid, and are mostly worn in Ireland. Buckskin is a close-grained and very strong leather for gloves; it has a little elasticity, and bears cleaning well. Sheepskin gloves are generally white, and are used for the army. Tan gloves are cheap and serviceable articles of a tan colour, for gardening, riding, and driving; the top is finished by a cuff formed by reversing the face of the leather. Beaver is an inappropriate name for the commonest kinds of leather gloves, mostly dyed drab. Woodstock is a kind of superior beaver, in which much attention is paid to cutting and sewing. Doeskin is a more substantial, durable, and soft leather than that employed for beaver or Woodstock gloves. Silk gloves are classed in quality partly according to the weight of silk, and partly to the neatness of the sewing. About the time of the Great Exhibition, silk gloves were introduced, cut upon the same principle as kid gloves; and these have since been much sought after, as presenting a better and neater fit than the general kinds of textile gloves. Berlin gloves were originally imported from Berlin; then from some parts of Switzerland: but now they are largely made in England, where they are considered to be very superior to the cotton gloves which they superseded. Thread gloves are made of flax, hemp, and cotton, according to their price and quality.

So far as concerns the English glovers as a body, it appears that in London they were incorporated by Charles I. in 1638, although they had long before formed a guild among themselves. The guild, as in nearly all cases, sought to create or maintain a monopoly; and the charter enabled them to do this. Deer and sheepskin gloves were the kinds chiefly made in London at that time; but after the introduction of kid gloves into England, the London makers took up that branch, and have ever since conducted it more successfully than the glovers of other parts of England. Worcester has produced gloves for nearly three hundred years; first of the beaver, or oil-leather kind, and then of the tanned or alumed leather, of which kid is an example. At Woodstock gloves have been made ever since the time of Queen Elizabeth. Ludlow, Leominster, and Yeovil, are other towns in which leather gloves are made. The introduction of knitted or looped fabrics for gloves, similar in texture to hosiery, has had the effect of removing much of the glove manufacture to the counties of Nottingham, Leicester, and Derby, where such fabrics are mostly made; this novelty, and the larger importation of French gloves on the lowering of the duty, have had the effect of reducing the manufacture of leather gloves in most of the above-named towns.

The economy of the glove manufacture is generally somewhat as follows. Taking Worcester as an example, the master-manufacturers live in the town, while the glove-sewers live in all the villages for many miles round about. These sewers are mostly the wives and daughters of country people, who eke out a scanty subsistence by this means. The leather employed mostly undergoes its preparatory preparation at some of the tanneries in Bermondsey, but it is finished at Worcester. The dressed skins are cut out in workshops, either by the shears and guide-pieces, or by cutting machines of quicker action. All the necessary thumb-pieces, finger-side pieces, &c., are cut out in proportionate number; and enough pieces for a dozen pairs are made up into a parcel. The sewers either send to the warehouse and take away the parcels of pieces, or agents of the manufacturer make a tour among the neighbouring villages at stated intervals, bring glove-pieces to be made up, take away the gloves which have been made since the last visit, and pay for the labour bestowed upon them: there may be branch establishments at a few of the villages, each of which is the centre of a district of glove-sewers. The sewers use a clasp or clam, which is held between the feet and knees, and which clasps the leather or leathers while being sewn; in some cases the sewer is aided by a kind of brass comb or notched plate, for ensuring regularity in the stitches. Some of the women and girls confine their attention to sewing the different pieces together; some work the ornamental stitching at the back of the glove, while others finish the top. It may here be remarked, however, that sewing-machines are gradually finding their way into the glove-trade; but it is only a portion of the work which can be done by their aid.

About ten years ago it was estimated that 46,000 persons were employed at glove making in England, producing gloves valued at about one million sterling annually. During the years 1856–7–8, French gloves were imported to the number of about 4,000,000 pairs annually.

GLUCIC ACID ($C_{24}H_{18}O_{18}$, 3HO); *Kalisaccharic acid.* Glucose, or grape sugar, forms, with bases, definite combinations, termed glucosides. Within a short time after the formation of such compounds their solutions are decomposable by a current of carbonic acid with separation of unaltered sugar; but even at ordinary temperatures they soon begin to undergo change; the liquid, at first powerfully alkaline, becomes neutral, and a substance of strongly acid character remains in combination with the base. To this substance is given the name *glucic acid.* On the addition of subacetate of lead to the neutral solution, sub-glucate of lead is precipitated, and this, on being decomposed by sulphuretted hydrogen, furnishes glucic acid.

Glucic acid is colourless and uncrystallisable, in appearance it somewhat resembles tannin, is very soluble in water and alcohol, has an acid taste, and combines with some bases to form neutral and acid salts. These salts are difficult to obtain in a crystallised condition; but the general formula of the neutral ones appears to be $C_{24}H_{15}M_3O_{18}$ + Aq.

When solution of glucic acid is boiled, it absorbs oxygen, becomes brown, and a new uncrystallisable acid is formed. To the latter Mulder gives the name *apoglucic* acid.

GLUCINA. [GLUCINUM.]

GLUCINUM (Gl.), the metallic base of an earth or oxide (*glucina*) discovered by Vauquelin in 1798, in the beryl, or aqua marina, and afterwards in the emerald. Before the discovery of potassium, glucina and all other earths were considered as simple substances. Glucinum was first obtained from glucina in 1827 by Wöhler, who procured it by decomposing the chloride of glucinum. Obtained in this mode, glucinum is a fine powder of a deep gray colour, which is very difficult of fusion. But, according to more recent experiments, it is, after fusion, a white malleable metal of sp. gr. 2·1, fusing at a lower heat than silver. It does not burn when heated in air or oxygen, neither does it decompose the vapour of water at a red heat.

Dilute acids and solution of potash dissolve glucinum, with the evolution of hydrogen gas, and its consequent conversion into glucina.

Glucina (Gl_2O_3), the only known oxide of the metal, is obtained from the minerals which contain it, by fusing with carbonate of potash, and treatment with acids and with carbonate of ammonia, which dissolves the glucina, and leaves the alumina unacted upon; the carbonate of ammonia being expelled by heat, pure glucina remains.

The properties of glucina are, that it is a light white powder, which has neither smell nor taste, infusible, insoluble in water and solution of ammonia, but soluble in potash and soda; its specific gravity is about 3.

Glucinum combines readily also with chlorine, iodine, bromine, sulphur, &c.

Chloride of glucinum (Gl_2Cl_3) is obtained by cautiously evaporating a solution of glucina in hydrochloric acid. The residue is colourless, sweet, very fusible and volatile, and sublimes readily in white brilliant needles; it deliquesces in the air, and dissolves largely in water with the extrication of heat. When procured by evaporation, it is a gummy mass, which contains water, and when heated in the air is decomposed into hydrochloric acid and glucina.

Sulphide of glucinum is formed by heating the metal in the vapour of sulphur. Much heat is given out, and a gray sulphide of the metal is obtained, which is soluble in water and decomposed by acids, with the evolution of hydrosulphuric acid.

The salts which glucina forms with acids are not important; we shall therefore mention only their general properties. They are all colourless, except the chromate, which is yellow; the taste is sweet, and hence the name of the earth, and slightly astringent. With potash and soda they give a white precipitate of hydrate of glucina, which an excess re-dissolves; but ammonia in excess does not re-dissolve the hydrate. The carbonate of ammonia in excess re-dissolves the precipitated carbonate, and so also do, slightly, the carbonates of potash and soda. Neither ferrocyanide of potassium nor tincture of galls gives any precipitate. With fluoride of potassium there is produced a double salt, which crystallises in small scales, provided the solutions are hot, and the admixture is continued till the solutions begin to be turbid.

GLUCOSE. [SUGAR.]

GLUCOSIDES. A number of vegetable substances which yield sugar under the influence of various chemical agents are comprehended under this term. The following is a list of the best known glucosides:—

Phloridzin ($C_{42}H_{24}O_{20}$, 4Aq.), when boiled with weak acids, is decomposed into grape-sugar and a resinous matter named *phloretin*:—

$$\underbrace{C_{42}H_{24}O_{20}}_{\text{Phloridzin.}} + 4HO = \underbrace{C_{12}H_{14}O_{14}}_{\text{Grape sugar.}} + \underbrace{C_{30}H_{14}O_{10}}_{\text{Phloretin.}}$$

Quercitrin ($C_{36}H_{18}O_{20}$ + 2Aq.) is transformed into *quercetin* and grape-sugar when boiled with dilute sulphuric or hydrochloric acids:—

$$\underbrace{C_{36}H_{18}O_{20}}_{\text{Quercitrin.}} + 4HO = \underbrace{C_{12}H_{14}O_{14}}_{\text{Grape sugar.}} + \underbrace{C_{24}H_{8}O_{16}}_{\text{Quercetin.}}$$

Arbutin ($C_{32}H_{22}O_{19}$), under the influence of synaptase, yields grape-sugar and *arcturin*:—

$$\underbrace{C_{32}H_{22}O_{19}}_{\text{Arbutin.}} + 2HO = \underbrace{C_{20}H_{10}O_{7}}_{\text{Arcturin.}} + \underbrace{C_{12}H_{14}O_{14}}_{\text{Grape sugar.}}$$

Esculin ($C_{42}H_{24}O_{26}$), when digested with synaptase or boiled with dilute acids, yields *esculetin* and grape-sugar:—

$$\underbrace{C_{42}H_{24}O_{26}}_{\text{Esculin.}} + 10HO = \underbrace{C_{18}H_{6}O_{8}}_{\text{Esculetin.}} + 2(\underbrace{C_{12}H_{14}O_{14}}_{\text{Grape sugar.}})$$

Descriptions of these glucosides are given under their respective names.

GLUE. [GELATINE.]

GLUTEN is the name given to the viscid, sticky, and more or less elastic substance that remains when wheaten flour, inclosed in a bag, has been well kneaded under water. It is exclusively a vegetable product, is a characteristic ingredient of all the cereal grains, but is notably contained in wheat and rye.

Gluten plays an important part in the manufacture of bread, a portion of it inducing alteration of the starch and subsequent fermentation, while another portion, on account of its elastic property, admits of the expansion or *rising* of the dough, and by its adhesive property gives permanence to that expansion by preventing the expanding gas from escaping. [BREAD.]

As an article of food, gluten is a nutritive or flesh-forming material, containing about 16 per cent. of nitrogen; and as large quantities of it are produced in the manufacture of wheat-starch, it has, under various forms, been introduced as an alimentary substance. *Gluten bread,* given to diabetic patients, may be readily made. *Gluten biscuits,* also have been proposed; and a kind of maccaroni or vermicelli, similar to the Italian pastes, was sometime since introduced into commerce. *Semola* is, essentially, wheat-flour from which a large proportion of the starch has been washed, and the residue dried and granulated.

Gluten is not a single definite body, but contains four distinct principles,—glutin, vegetable fibrin, vegetable casein, and an oily matter. [FIBRIN; GLIADIN.] Gluten is soluble in cold acetic acid and weak alkaline solutions; from these liquids it is again precipitated on carefully neutralising. The mineral acids form compounds with it. In the dry state it forms a brown horny-looking mass, that may be preserved for any length of time; but in the moist condition it rapidly putrefies.

GLUTIN. [Gliadin.]

GLYCERAMINE. [Glycerin.]

GLYCERIC ACID ($C_6H_6O_8$). This body was first discovered by Debus, who obtained it by the oxidation of glycerin by means of nitric acid. One part of glycerin mixed with its volume of water is placed in an upright cylinder, and one part of strong nitric acid allowed to flow underneath the glycerin. The two layers gradually mix, and oxidation takes place with disengagement of gas. After the action is over, the product is evaporated in small quantities in the water bath, diluted with water, neutralised with chalk, and strong alcohol added, which precipitates the lime salts. These are then dissolved in warm water, filtered, and to the filtrate excess of milk of lime is added, which precipitates certain impurities. The liquid is again filtered, the free lime removed by carbonic acid, and the liquid evaporated to crystallisation.

The acid is obtained by precipitating the lime-salt with oxalic acid, and evaporating the filtrate in the water bath. In its state of greatest concentration it is a thick yellowish syrup, which dried at 284° Fahr. has the appearance of gum arabic. It readily attracts moisture. Its aqueous solution decomposes carbonates, coagulates milk, and dissolves iron and zinc with disengagement of gas. The salts of glyceric acid crystallise well; they have the general formula $C_6H_5MO_8$.

Glyceric acid can be considered as being derived from glycerin in the same manner as glycolic acid from glycol, or as acetic acid is derived from ordinary alcohol:—

$$\underbrace{\left.\begin{matrix}C_4H_5\\H\end{matrix}\right\}O_2}_{\text{Alcohol.}} \qquad \underbrace{\left.\begin{matrix}C_4H_4''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} \qquad \underbrace{\left.\begin{matrix}C_6H_5'''\\H_3\end{matrix}\right\}O_6}_{\text{Glycerin.}}$$

$$\underbrace{\left.\begin{matrix}C_4H_3O_2\\H\end{matrix}\right\}O_2}_{\text{Acetic acid.}} \qquad \underbrace{\left.\begin{matrix}(C_4H_2O_2)''\\H_2\end{matrix}\right\}O_4}_{\text{Glycolic acid.}} \qquad \underbrace{\left.\begin{matrix}(C_6H_3O_2)'''\\H_3\end{matrix}\right\}O_6}_{\text{Glyceric acid.}}$$

According to this view of its constitution, glyceric acid is tribasic. But the salts of glyceric acid, as far as they have been examined, are monobasic. In order to decide the question as to the basicity of glyceric acid, the ethers and the amides ought to be investigated; until this is done, the formula may be written $\left.\begin{matrix}(C_6H_3O_2''')\\H_3\end{matrix}\right\}O_6$ although it must be confessed that at present this view is nothing more than a probable hypothesis.

GLYCERIDES. [Glycerin.]

GLYCERIN ($C_6H_8O_6$), *Hydrated oxide of lipyl.* This substance was discovered by Scheele in 1779, who obtained it in the preparation of lead plaster. He named it, "sweet principle of oils," from its sweet taste. Subsequently, its properties were more accurately studied by Chevreul in his classical investigations on the chemical history of bodies of fatty origin, and by Pelouze. Recently Berthelot and De Luca have greatly extended our knowledge of this substance.

Most of the fats and oils of the animal and vegetable kingdoms have a constitution analogous to that of the compound ethers,—acetic ether, for example. When that substance is treated with alkalies it assimilates the elements of water, forming an alkaline acetate and alcohol. Oils and fats in like manner undergo by the same treatment a similar change. They assimilate the elements of water, glycerin is set free, and a salt of the acid, previously in combination with glycerin, is formed. On this decomposition the methods of preparing glycerin are based.

Glycerin may be prepared by saponifying oils with oxide of lead: equal parts of olive oil and of finely powdered litharge are mixed in a basin with water, the mixture heated to boiling for some time, and continually stirred, water being added to replace that which evaporates. Insoluble lead salts (in this case, the oleate and stearate of lead) are formed; warm water is then added, and the aqueous liquid decanted, filtered, and sulphuretted hydrogen passed through the filtrate, in order to precipitate a small quantity of oxide of lead, which dissolves. The filtered liquid is then evaporated in vacuo, or over the water bath.

Glycerin is also obtained as a by-product in the manufacture of stearin candles, in which case, the saponification is effected by means of lime.

But the simplest method, and that to which we owe the abundant and cheap supply of glycerin met with in commerce, is the one introduced by Wilson. It consists in treating the fats in a suitable distilling apparatus with superheated steam. The fats assimilate the elements of water, and are decomposed into their constituents—the fatty acids and glycerin. Both distil over, and form in the recipient two layers of liquid, of which the lower is tolerably pure aqueous glycerin. To purify it still further it may be again distilled with high pressure steam, concentrated in the water bath, and ultimately in vacuo over sulphuric acid.

Pure glycerin is a colourless, viscous, neutral, inodorous liquid, with a sweet taste, from whence it derives its name (γλυκός, sweet). It is uncrystallisable; at 40° Fahr. it becomes gummy, and almost solid. It is miscible with water and alcohol in all proportions, but is insoluble in ether. It attracts moisture from the air, and becomes more limpid. Concentrated as far as possible in vacuo over sulphuric acid, it has the sp. gr. 1·285 at 150° Fahr. It is difficultly volatile, and only begins to distil unchanged at 518° Fahr. When its aqueous solution is distilled some glycerin passes off with the vapour.

Pasteur has found that glycerin is contained in all fermented liquors, and more especially in wine. Its quantity amounts to 3 per cent. of the fermented sugar.

Decomposition of glycerin.—When glycerin is rapidly heated in a closed vessel above its boiling point, it is decomposed, with formation of inflammable gases, acetic acid, and acrolein. Derivatives of glycerin also, such as the natural oils and fats, by destructive distillation, yield acrolein, the characteristic odour of which readily indicates the presence of glycerin in any of these bodies.

Mixed with platinum black, and placed in oxygen, glycerin absorbs a large quantity of this gas, with the formation of inadequately investigated acid products, probably containing glyceric acid, which are ultimately oxidised to carbonic acid and water.

When an aqueous solution of glycerin is exposed in contact with yeast to a temperature of 68–85° Fahr. for several months, a large quantity of propionic acid is produced, together with some formic and acetic acids.

According to Berthelot, glycerin passes by fermentation into alcohol, when it is left for some time in contact with chalk and decaying cheese to a temperature of 85–105° Fahr.

When glycerin is gently heated with hydrate of potash or soda, it is converted into acetate and formiate, with liberation of hydrogen. Acrolein appears to be first formed, this then passes into acrylic acid, which in turn is resolved into acetic and formic acids.

In contact with anhydrous phosphoric acid, glycerin becomes strongly heated, and acrolein is disengaged; this is also the case when it is distilled with bisulphate of potash.

Strong nitric acid converts glycerin in a great measure into *glyceric acid*, $C_6H_6O_8$. By a mixture of strong nitric and sulphuric acids, it is converted into *nitro-glycerin* $C_6H_5O_3, 3NO_5$.

The oily nature of glycerin, its property of not solidifying, even when exposed to great cold, its permanency, its pleasant taste, its solvent powers, and the cheap rate at which it can be procured, will eventually secure for it an extensive use in pharmacy, arts, and manufactures. A few of its applications may be here mentioned.

It has been used to preserve articles of food, botanical and zoological preparations. When added to confectionary wares, preserved fruits, and chocolate, it serves to prevent them from becoming dry. It serves a similar purpose in the manufacture of tobacco and snuff. The water in gas-meters is liable to freeze in winter, and evaporate too rapidly in summer; the addition of glycerin prevents these evils. Glycerin is also used in the manufacture of copying ink, and in lubricating. It is also used, under a patent, in preparing paper for dry printing.

Glycerides, and constitution of glycerin.—The glycerides are the compound ethers of glycerin. To understand their nature the constitution of glycerin must be understood, and the two points can best be discussed together.

The natural fats and oils, as previously stated, have a constitution analogous to that of the compound ethers. This view of their composition was first propounded by Chevreul. Afterwards, Duffy, in an investigation of stearin, found that the quantity of stearine, which in saponifying forms one equivalent of stearic acid, only forms one-third of an equivalent of glycerin. Subsequently, Berthelot succeeded in artificially forming a large quantity of the natural fats, by directly combining the acids with glycerin, and it is on these researches, and on an interpretation of them proposed by Wurtz, that the prevailing views of their constitution are based. Berthelot found that the acids could be made to combine with glycerin in three different proportions, with elimination of the elements of water, and he characterised glycerin as a polyacid alcohol, that is, as an alcohol in which several equivalents of hydrogen are replaceable by acid radicals to form ethers. He considered glycerin as bearing to alcohol a somewhat similar relation to that which tribasic phosphoric acid bears to nitric acid.

Ordinary alcohol we may consider to be derived from the type of a double atom of water $\left.\begin{matrix}H\\H\end{matrix}\right\}O_2$ by the substitution of the monoatomic radical ethyl for an atom of hydrogen; and a compound ether is alcohol, in which another atom of hydrogen is replaced by an acid radical, such as acetyl. Thus:—

$$\underbrace{\left.\begin{matrix}H\\H\end{matrix}\right\}O_2}_{\text{Water.}} \qquad \underbrace{\left.\begin{matrix}C_4H_5\\H\end{matrix}\right\}O_2}_{\text{Alcohol.}} \qquad \underbrace{\left.\begin{matrix}C_4H_5\\C_4H_3O_2\end{matrix}\right\}O_2}_{\text{Acetic ether.}}$$

In like manner we may consider glycerin to be derived from the type of *three* double atoms of water by the substitution of the teratomic radical C_6H_5''' for three atoms of hydrogen. Thus:—

$$\underbrace{\left.\begin{matrix}H_3\\H_3\end{matrix}\right\}O_6}_{\text{3 atoms of water.}} \qquad \underbrace{\left.\begin{matrix}C_6H_5'''\\H_3\end{matrix}\right\}O_6}_{\text{Glycerin.}}$$

This view of the constitution of glycerin is supported by an experiment of Wurtz, in which he succeeded in obtaining glycerin artificially. By the action of terbromide of allyl, $C_6H_5'''Br_3$, on acetate of silver, a body is formed which has the composition and all the properties of triacetin. When this body is decomposed by baryta water, acetate of baryta and glycerin are formed. Terbromide of allyl is not a derivative of glycerin, it belongs to the allylic alcohol series. The following re-actions exhibit the change :—

$$\underbrace{\left.\begin{matrix}C_6H_5''' \\ Br_3\end{matrix}\right\}}_{\text{Terbromide of allyl.}} + \underbrace{3\left.\begin{matrix}C_4H_3O_2 \\ Ag\end{matrix}\right\}O_2}_{\text{Acetate of silver.}} = \underbrace{3AgBr}_{\text{Bromide of silver.}} + \underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_4H_3O_2)_3\end{matrix}\right\}O_6}_{\text{Triacetin.}}$$

$$\underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_4H_3O_2)_3\end{matrix}\right\}O_6}_{\text{Triacetin.}} + \underbrace{3BaO\,HO}_{\text{Hydrate of baryta.}} = \underbrace{\left.\begin{matrix}C_6H_5''' \\ H_3\end{matrix}\right\}O_6}_{\text{Glycerin.}} + \underbrace{3\left(\left.\begin{matrix}C_4H_3O_2 \\ Ba\end{matrix}\right\}O_2\right)}_{\text{Acetate of baryta.}}$$

In alcohol there is only one atom of hydrogen replaceable by a radical to form a compound ether. In glycerin there are three atoms capable of being replaced, and accordingly we may have three series of ethers, thus :—

$$\left.\begin{matrix}(C_6H_5)''' \\ R \\ H \\ H\end{matrix}\right\}O_6 \qquad \left.\begin{matrix}(C_6H_5)''' \\ R \\ R \\ H\end{matrix}\right\}O_6 \qquad \left.\begin{matrix}(C_6H_5)''' \\ R \\ R \\ R\end{matrix}\right\}O_6.$$

All these three classes are represented by compounds, some of which have been prepared directly from their constituents, and some exist already formed in nature. The glycerides which compose the natural fats are almost all normal neutral glycerides, that is, they contain 3 eq. of hydrogen replaced by 3 eq. of an acid radical, and the natural fats are almost all mixtures of several of these glycerides.

From the above view of the constitution of glycerin. it is obvious that a great number of glycerides may exist, according as 1, 2, or 3 eq. of hydrogen are replaced by 1, 2, or 3 of the same or different acid radicals. We may also have glycerides of the following composition :—

$$\left.\begin{matrix}(C_6H_5)''' \\ R'' \\ H\end{matrix}\right\}O_6 \qquad \left.\begin{matrix}(C_6H_5)''' \\ R'' \\ R\end{matrix}\right\}O_6 \qquad \left.\begin{matrix}(C_6H_5)''' \\ R'''\end{matrix}\right\}O_6$$

It is evident that glycerin may give rise to the formation of a great number of ethers, according as the atoms of hydrogen are replaced by different monoatomic radicals, or by a biatomic radical, or by a teratomic radical, where R'' and R''' are respectively biatomic and teratomic radicals.

The natural glycerides have been named by adding to an abbreviation of the name of the acid, the termination *in*, thus we have *stearin*, *olein*, &c. The artificial fats have been named in accordance with this principle, and the prefixes mono-, di-, and tri-, express respectively the proportions of the radical contained in them. Thus we have :—

$$\underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_{36}H_{35}O_3) \\ H_2\end{matrix}\right\}O_6}_{\text{Monostearin.}} \qquad \underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_{36}H_{35}O_3)^2 \\ H\end{matrix}\right\}O_6}_{\text{Distearin.}} \qquad \underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_{36}H_{35}O_2)^3\end{matrix}\right\}O_6}_{\text{Tristearin.}}$$

Similarly we have :—

$$\underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_4H_3O_2) \\ H_2\end{matrix}\right\}O_6}_{\text{Monoacetin.}} \qquad \underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_4H_7O_2)^2 \\ H\end{matrix}\right\}O_6}_{\text{Diacetin.}} \qquad \underbrace{\left.\begin{matrix}C_6H_5''' \\ (C_4H_3O_2)^3\end{matrix}\right\}O_6}_{\text{Triacetin.}}$$

According to Berthelot, the artificial fats are formed by heating the hydrated acids along with glycerin in closed vessels for some time to a more or less elevated temperature. Many of them are formed even at the ordinary temperature. The glycerides containing 1 eq. of acid are mostly obtained by the continued heating of a mixture of hydrated acid with excess of glycerin to a temperature of 392° Fahr.

Of those containing 2 eq. of acid, some are obtained by continuously heating glycerin with excess of acid to a temperature of 392° Fahr. In some cases combination takes place at 212° Fahr.; in others the temperature requires to be raised to 527° Fahr.

The neutral compounds are obtained by heating the above compounds with excess of acid to a temperature of from 464° Fahr. to 500° Fahr.

In many cases the glycerides may be obtained by saturating a mixture of glycerin and the acid with hydrochloric acid, and heating to 212° Fahr.

The combination of glycerin with the acid takes place with the loss of water—a double atom of water being separated for every equivalent of acid. Thus :—

$$\underbrace{C_6H_8O_6}_{\text{Glycerin.}} + \underbrace{C_4H_4O_4}_{\text{Acetic acid.}} = 2HO + \underbrace{C_{10}H_{10}O_8}_{\text{Monoacetin.}}$$

$$C_6H_8O_6 + 2(C_4H_4O_4) = 4HO + \underbrace{C_{14}H_{12}O_{10}}_{\text{Diacetin.}}$$

$$C_6H_8O_6 + 3(C_4H_4O_4) = 6HO + \underbrace{C_{18}H_{14}O_{12}}_{\text{Triacetin.}}$$

Besides combining glycerin with the fatty acids, Berthelot has obtained combinations with the mineral acids. A brief notice of the hydrochloric and nitric acid compounds will be given here ; and most of the glycerides will be described under their respective heads. But for further information on the subject, the reader must be referred to the original papers of Berthelot which have appeared in the 'Annales de Chimie et Physique,' vols. xli and xliii.

Glycerin forms with hydrochloric acid three combinations, which have been named monochlorhydrin, dichlorhydrin, and trichlorhydrin.

Monochlorhydrin $\left(C_6H_7ClO_4 = \left.\begin{matrix}C_6H_5''' \\ H_2 \\ Cl\end{matrix}\right\}O_4\right)$ is obtained by saturating glycerin with hydrochloric acid gas, and maintaining the solution for a long time at a temperature of 212° Fahr. It is then neutralised with carbonate of soda, and agitated with ether. On evaporating this solution, the body is left as a neutral oil, of a fresh and ethereal odour, and a sweet but fragrant taste. It is miscible with water and ether. Its density is 1·31, and it boils at 441° Fahr. Monochlorhydrin acts on ammonia, and forms the hydrochlorate of a base which Berthelot names *glyceramine*.

$$\underbrace{C_6H_7O_4,Cl}_{\text{Monochlorhydrin.}} + NH_3 = \underbrace{N\left\{\begin{matrix}C_6H_7O_4 \\ H \\ H\end{matrix}\right.}_{\text{Hydrochlorate of glyceramine.}} + HCl$$

Dichlorhydrin $\left(C_6H_6Cl_2O_2 = \left.\begin{matrix}C_6H_5''' \\ H \\ Cl_2\end{matrix}\right\}O_2\right)$ is obtained by exposing a mixture of glycerin with ten to twelve times its bulk of fuming hydrochloric acid to a temperature of 212° Fahr. for several days. It is purified like the preceding compound. It has a strong ethereal odour ; dissolves readily in ether, but with greater difficulty in water than monochlorhydrin. It boils at 352° Fahr. It is decomposed by alkalies into chlorides and glycerin.

Trichlorhydrin, $C_6H_5Cl_3 = \left.\begin{matrix}C_6H_5''' \\ Cl_3\end{matrix}\right\}$ obtained by treating dichlorhydrin with pentachloride of phosphorus ; it is a neutral liquid, boiling at 311° Fahr.

The formation of these ethers may be thus expressed :—

$$\underbrace{C_6H_8O_6}_{\text{Glycerin.}} + HCl = \underbrace{C_6H_7O_4Cl}_{\text{Monochlorhydrin.}} + 2HO$$

$$\underbrace{C_6H_8O_6}_{\text{Glycerin.}} + 2HCl = \underbrace{C_6H_6O_2Cl_2}_{\text{Dichlorhydrin.}} + 4HO$$

$$\underbrace{C_6H_8O_6}_{\text{Glycerin.}} + 3HCl = \underbrace{C_6H_5Cl_3}_{\text{Trichlorhydrin.}} + 6HO$$

Nitroglycerin, Glonoin $\left.\begin{matrix}C_6H_5''' \\ (NO_4)^3\end{matrix}\right\}O^6$, the nitric ether of glycerin. This substance is prepared by gradually adding glycerin to a mixture of sulphuric and fuming nitric acids, carefully cooled. The glycerin dissolves without any disengagement of nitric vapours. On adding water to the solution, nitroglycerin is precipitated as a heavy yellowish oil, soluble in alcohol and ether, with a saccharine and aromatic taste. It is a very instable compound. It decomposes with a loud detonation when heated, and explodes even when struck violently. A solution of nitroglycerin, left to stand for some time, decomposes into glyceric acid. A drop of nitroglycerin placed on the tongue causes a sensation of nausea, which lasts for several hours.

Nitroglycerin appears to possess different properties, according to the mode of its formation. Probably in some cases a basic nitrate is formed.

Glyceric Ether. The replacement of both the hydrogen atoms in alcohol by ethyl produces ether $\left.\begin{matrix}C_4H_5 \\ C_4H_5\end{matrix}\right\}O_2$. The compound exactly corresponding to ether in the series of glycerin is not known, but a substance exists which corresponds to the mixed ethers of Williamson This is *diathylin*. It is prepared by heating a mixture of glycerin, caustic potass, and bromide of ethyl, to a temperature of 100° for several days. It is a colourless limpid oil, with a slightly aromatic ethereal odour. Its sp. gr. is 0·920, and it boils at 376° Fahr. Its formula is $C_{14}H_{16}O_6$, and it is glycerin in which 2 equivalents of hydrogen are replaced by 2 equivalents of ethyl $\left.\begin{matrix}C_6H_5{}'''\\(C_4H_5)_2\\H\end{matrix}\right\}O_6$.

Glycerin, when treated with sulphuric, phosphoric, or tartaric acids, combines with them, forming compounds analogous to sulphovinic, phosphovinic, and tartrovinic acids.

Sulphoglyceric Acid ($C_6H_8S_2O_{12}$). When glycerin is mixed in the cold with double its weight of concentrated sulphuric acid, the two substances combine with considerable elevation of temperature, but without producing any colouring. The mixture is cooled, diluted with water, and then saturated with baryta, by which a crystallisable sulphoglycerate of baryta is formed. By treating a solution of this substance with sulphuric acid, sulphate of baryta is formed, and sulphoglyceric acid set free. The aqueous solution of the latter must be concentrated in vacuo, and the concentration cannot exceed a certain limit, otherwise decomposition takes place, even at 32° Fahr. The sulphoglycerates are mostly soluble in water; they are very readily decomposed by being heated with water or metallic oxides, forming sulphuric acid and glycerin. By dry distillation they are decomposed, with formation of sulphurous acid, acrylic acid, acrolein, &c.

Sulphoglyceric acid is analogous to sulphovinic acid. If this latter be considered as sulphuric acid in which one atom of hydrogen has been replaced by ethyl, then the corresponding compound of glycerin may be represented as sulphuric acid in which one atom of hydrogen is replaced by the monatomic group $C_6H_7O_4$ derived from glycerin. The same remark would apply to phosphoglyceric and tartroglyceric acids. The formation of sulphoglyceric acid is thus expressed:—

$$\underbrace{\left.\begin{matrix}C_6H_7O_4\\H\end{matrix}\right\}O_2}_{\text{Glycerin.}} + \underbrace{\left.\begin{matrix}S_2O_4\\H_2\end{matrix}\right\}O_4}_{\text{Sulphuric acid.}} = \left.\begin{matrix}H\\H\end{matrix}\right\}O_2 + \underbrace{\left.\begin{matrix}S_2O_4\\C_6H_7O_4\\H\end{matrix}\right\}O_4}_{\text{Sulphoglyceric acid.}}$$

Phosphoglyceric acid ($C_6H_8O_6,PO_5HO$). This body is obtained by dissolving glacial phosphoric acid in its weight of syrupy glycerin. The solution is accompanied by considerable rise of temperature. It is then diluted with water, neutralised with baryta, filtered from the insoluble phosphate of baryta, and the concentrated filtrate mixed with solution of acetate of lead, by which an insoluble phosphoglycerate of lead is formed. To obtain the acid, this salt is decomposed with sulphuretted hydrogen, and the filtrate evaporated and concentrated in vacuo. It is an uncrystallisable liquid, which at its state of greatest concentration has the consistence of a thick syrup. In this state it is readily decomposed by an increase of temperature into glycerin and free phosphoric acid.

The phosphoglycerates are generally soluble in water, but little or not at all in alcohol. Their solutions decompose by boiling, especially in the presence of bases, into phosphates and free glycerin.

M. Goblez has found that phosphoglyceric acid in combination with soda and ammonia is contained in the cerebral matter, and in the yolk of egg.

When glycerin is heated with anhydrous phosphoric acid, acrolein is produced. [ACROLEIN.]

GLYCERYL (C_6H_7). The radical formerly assumed to be contained in GLYCERIN, the formula of which was then written $C_6H_7O_5$, HO. Recent researches prove that the compound group, which in glycerin occupies the same position as ethyl in alcohol, is the teratomic radical C_6H_5, to which therefore the above term would now be more appropriately applied.

GLYCOCIN. [GLYCOCOLL.]

GLYCOCOLL, *Glycocin. Sugar of gelatine*, $C_4NH_5O_4$, is a compound found amongst the products obtained by boiling gelatine with potash or acids. It may also be prepared by heating hippuric acid with hydrochloric acid, when benzoic acid, water, and glycocoll are produced. It forms transparent crystals, which are soluble in water and sweet to the taste. It combines with acids and bases. Its easy formation from the animal compound gelatine, has led to the supposition that it may play an important part in the animal body.

GLYCOL ($C_4H_6O_4$). This is the type of a new class of compounds discovered by Wurtz in 1856. In their chemical relations and properties they occupy a place intermediate between the class of alcohols of which common alcohol is the type, on the one hand, and the class of bodies of which glycerin is the type, on the other. The name *glycol* has been given to express this relation, and that of *biatomic alcohol* to express that they have a capacity of saturation double that of common alcohol.

We may consider alcohol as being derived from the type of a double atom of water by the substitution of an equivalent of the monoatomic radical ethyl for an equivalent of hydrogen. [ORGANIC RADICALS.]

If now in *two* double atoms of water we replace *two* eq. of hydrogen by a biatomic radical, such as ethylene, C_4H_4, we shall obtain glycol. The relations of alcohol to glycol may be thus seen.

$$\underbrace{\left.\begin{matrix}C_4H_5\\H\end{matrix}\right\}O_2}_{\text{Alcohol.}} \qquad \underbrace{\left.\begin{matrix}C_4H_4{}''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}}$$

By the action of iodide of ethyl, for example, on acetate of silver we obtain iodide of silver and acetic ether. Similarly by the action of the biatomic iodide of ethylene ($C_4H_4I_2$) on two equivalents of acetate of silver we obtain acetate of glycol, the acetic ether of glycol:—

$$\underbrace{2\left(\left.\begin{matrix}C_4H_3O_2\\Ag\end{matrix}\right\}O_2\right)}_{\text{Acetate of silver.}} + \underbrace{C_4H_4{}''I_2}_{\text{Iodide of ethylene.}} = \underbrace{\left.\begin{matrix}C_4H_4{}''\\(C_4H_3O_2)_2\end{matrix}\right\}O_4}_{\text{Acetate of glycol.}} + \underbrace{2AgI}_{\text{Iodide of silver.}}$$

It was by means of this re-action that Wurtz first obtained the acetic ether of glycol, and from the ether, by decomposition with alkalies, glycol itself. The method is suceptible of general application, and by its means Wurtz has already obtained four members of the series: ethyl glycol, propyl glycol, butyl glycol, and amyl glycol.

We shall describe the preparation and properties of the typical member of the group glycol itself. It will not be necessary to enter minutely into a consideration of the others, inasmuch as they present the most perfect homology with glycol, not only in their properties, but in their chemical relations.

For the preparation of glycol, the best method is that proposed by Atkinson. It is a modification of Wurtz's method, and consists in the action of bromide of ethylene on acetate of potash. The products of the re-action are bromide of potassium, free acetic acid, and monoacetate of glycol, as is seen by the equation—

$$\underbrace{2\left(\left.\begin{matrix}C_4H_3O_2\\K\end{matrix}\right\}O_2\right)}_{\text{Acetate of potash.}} + \underbrace{C_4H_4{}''Br_2}_{\text{Bromide of ethylene.}} = \underbrace{\left.\begin{matrix}C_4H_4{}''\\(C_4H_3O_2)\\H\end{matrix}\right\}O_4}_{\text{Monoacetate of glycol.}} + \underbrace{C_4H_4O_4}_{\text{Acetic acid.}} + \underbrace{2KBr}_{\text{Bromide of potassium.}}$$

About 2 ounces of acetate of potash, dissolved in 5 or 6 ounces of alcohol, are placed in a soda-water bottle with 2 ounces of bromide of ethylene: the bottle is lightly corked, and heated for two days on the water-bath. The contents are then filtered from the bromide of potassium, which is washed with ether, and the united filtrates and washings submitted to fractional distillation, those parts being collected which distil above 356° Fahr. On being again rectified, the greater part, consisting of pure monoacetate of glycol, distils over at 360° Fahr.

To obtain glycol, the monoacetate of glycol is mixed with an equivalent quantity of potash, which decomposes it with evolution of heat. The mixture after having been allowed to stand some time, is distilled in the oil bath. On rectifying the distillate, a product is obtained, boiling at 387° Fahr., which is pure glycol. The decomposition of monoacetate of glycol by potash is expressed by the equation:—

$$\underbrace{\left.\begin{matrix}C_4H_4{}''\\C_4H_3O_2\\H\end{matrix}\right\}O_4}_{\text{Monoacetate of glycol.}} + KO\,HO = \underbrace{\left.\begin{matrix}C_4H_4{}''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} + \underbrace{C_4H_3KO_4}_{\text{Acetate of potash.}}$$

The following modification of this method has been used by Debus, and although somewhat tedious it gives a larger product. Monoacetate of glycol mixed with its bulk of water is heated for 12 to 16 hours in a closed vessel to the temperature of boiling water. By this means it is decomposed into free acetic acid and glycol. The liquid is rectified, and the parts collected which distil over above 374° Fahr. This consists principally of glycol, but still contains acetic acid.

An acetic acid determination, by means of baryta, is made in a sample of this liquid, and then the proportionate quantity of potash is added, and the mixture submitted to distillation. The distillate consists of pure glycol.

Pure glycol is an inodorous, somewhat viscid, liquid, with a slightly saccharine taste. It has a density of 1·125 at 32° Fahr. It boils at 386° to 387° Fahr. Exposed to the temperature produced by a mixture of solid carbonic acid and ether, it becomes gummy without solidifying. Its vapour density has been found to be 2·164. The number required by theory is 2·146.

Glycol is perfectly soluble in water and in alcohol, but only slightly so in ether. In this respect it resembles glycerin. In its solvent properties it stands between water and alcohol. In its chemical re-actions it presents, as will be seen, the closest analogy with alcohol.

Glycol is unaltered in the air; but mixed with platinum black it attracts oxygen with such avidity that the platinum becomes incandescent. By regulating the conditions of the experiment, however, so as to produce a slow action, an aqueous solution of glycol is slowly converted into glycolic acid.

Potassium attacks glycol with energy; hydrogen is evolved, and the heat disengaged is so intense as to inflame the gas, and blacken the residue. The action of sodium is less violent—hydrogen gas is disengaged, and the liquid is converted into a solid white mass consisting of *monosodium glycol*, $\left.\begin{matrix}C_4H_4''\\Na\\H\end{matrix}\right\}O_4$. By heating this compound with an additional equivalent of sodium to a temperature of 374° Fahr. another equivalent of hydrogen is replaced by sodium—the *disodium glycol* $\left(\left.\begin{matrix}C_4H_4''\\Na_2\end{matrix}\right\}O_4\right)$ being formed.

Nitric acid oxidises glycol with great energy, with formation of glyoxylic, glycolic, and oxalic acids.

When glycol is fused with hydrate of potash, a large quantity of hydrogen gas is disengaged, and the residue consists principally of oxalate of potash. Alcohol, under similar treatment, yields hydrogen and acetate of potash:

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} + 2KO\,HO = \underbrace{\left.\begin{matrix}C_4O_4\\K_2\end{matrix}\right\}O_4}_{\text{Oxalate of potash.}} + 8H$$

The action of pentachloride of phosphorus on glycol is very energetic; the products formed are hydrochloric acid, oxychloride of phosphorus, and chloride of ethylene.

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} + \underbrace{2PCl_5}_{\substack{\text{Pentachloride}\\\text{of phosphorus.}}} = \underbrace{C_4H_4''Cl_2}_{\substack{\text{Chloride of}\\\text{ethylene.}}} + \underbrace{2PO_2Cl_3}_{\substack{\text{Oxychloride}\\\text{of phosphorus.}}} + 2HCl$$

Chloride of ethylene is the true hydrochloric ether of glycol—it stands towards it in the same relation as chloride of ethyl to alcohol.

Ethers of glycol.—The ether of glycol is not formed by the ordinary processes of etherification. When glycol is treated with chloride of zinc, aldehyde is formed, and Wurtz was at first inclined to regard this as the ether corresponding to glycol. The true ether is, however, obtained by the action of potash on monohydrochlorate of glycol:—

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H\\Cl\end{matrix}\right\}O_2}_{\substack{\text{Monochlorhydrate}\\\text{of glycol.}}} + KO\,HO = \underbrace{C_4H_4O_2}_{\substack{\text{Glycolic}\\\text{ether.}}} + \underbrace{KCl}_{\substack{\text{Chloride of}\\\text{potassium.}}} + 2HO$$

The action takes place with considerable energy, chloride of potassium is formed, and a gas disengaged which is condensed by means of a freezing mixture to a very mobile liquid, boiling at 56° Fahr. Its vapour density is 1·42. The calculated number is 1·52.

It is isomeric with aldehyde, which it resembles in many respects. It reduces ammoniacal nitrate of silver—but unlike aldehyde, it forms no crystalline compound with ammonia. By the action of pentachloride of phosphorus, glycolic ether yields chloride of ethylene,—

$$\underbrace{C_4H_4O_2}_{\text{Glycolic ether.}} + PCl_5 = PO_2Cl_3 + \underbrace{C_4H_4Cl_2}_{\substack{\text{Chloride of}\\\text{ethylene.}}}$$

By the same treatment, aldehyde yields chloride of aldehydene.

Two mixed ethers, corresponding to the mixed ethers of Williamson, have been obtained from glycol. The first, *ethylglycol* $\left(\left.\begin{matrix}C_4H_4''\\(C_4H_5)\\H\end{matrix}\right\}O_4\right)$, is obtained by the action of iodide of ethyl on monosodium glycol:—

$$\underbrace{\left.\begin{matrix}C_4H_4\\Na\\H\end{matrix}\right\}}_{\substack{\text{Monosodium}\\\text{glycol.}}} + \underbrace{C_4H_5I}_{\substack{\text{Iodide of}\\\text{ethyl.}}} = \underbrace{\left.\begin{matrix}C_4H_4''\\(C_4H_5)\\H\end{matrix}\right\}O_4}_{\text{Ethylglycol.}} + \underbrace{NaI}_{\substack{\text{Iodide of}\\\text{sodium.}}}$$

When monoethylglycol is treated with potassium, hydrogen is liberated and a white solid mass formed, which, when treated with iodide of ethyl, yields *diethylglycol*:—

$$\left.\begin{matrix}C_4H_4''\\C_4H_5\\K\end{matrix}\right\}O_4 + \underbrace{C_4H_5I}_{\substack{\text{Iodide of}\\\text{ethyl.}}} = \underbrace{KI}_{\substack{\text{Iodide of}\\\text{potassium.}}} + \underbrace{\left.\begin{matrix}C_4H_4''\\(C_4H_5)_2\end{matrix}\right\}O_4}_{\text{Diethylglycol.}}$$

Diethylglycol is a colourless mobile liquid, with an agreeable ethereal odour. Its sp. gr. is 0·7993, and its vapour density, 4·095. Theory requires 4·085. Its boiling point is 254° Fahr. In this respect it differs from acetal, with which it is isomeric, which boils at 217° Fahr.

Compound ethers of glycol.—The compound ethers of the alcohol series are formed by the union of

Alcohol + acid — 2 at. Water.

as in the formation of acetic ether:—

$$\underbrace{C_4H_6O_2}_{\text{Alcohol.}} + \underbrace{C_4H_4O_4}_{\text{Acetic acid.}} - 2HO = \underbrace{\left.\begin{matrix}C_4H_5\\(C_4H_3O_2)\end{matrix}\right\}O_2}_{\text{Acetic ether.}}$$

In an analogous manner the compound ethers of glycol are derived by the union of glycol + 2 at. acid — 4 at. water, as in the formation of acetate of glycol:—

$$\underbrace{C_4H_6O_4}_{\text{Glycol.}} + \underbrace{2C_4H_4O_4}_{\text{Acetic acid.}} - 4HO = \underbrace{\left.\begin{matrix}C_4H_4''\\(C_4H_3O_2)_2\end{matrix}\right\}O_4}_{\text{Acetate of glycol.}}$$

In saponifying, the compound ethers of alcohol assimilate 2 at. water whilst the compound ethers of glycol assimilate 4 at. water. The compound ethers of glycol are in general prepared by the action of the iodide or bromide of ethylene on the corresponding silver salt.

Acetate of glycol $\left(C_{12}H_{10}O_8=\left.\begin{matrix}C_4H_4''\\(C_4H_3O_2)_2\end{matrix}\right\}O_4\right)$; is formed by the action of iodide or bromide of ethylene on acetate of silver in the presence of free acetic acid. It is a colourless neutral liquid, with a slight acetic odour. It boils at 367° Fahr. It dissolves in 7 volumes of water at 71° Fahr.

Monoacetate of glycol $\left(C_8H_8O_6=\left.\begin{matrix}C_4H_4''\\C_4H_3O_2\\H\end{matrix}\right\}O_4\right)$. The preparation and properties of this body have been already described. It is also formed when anhydrous acetic acid acts on glycol. When heated for some time in a closed vessel with water, it is decomposed into glycol and free acetic acid.

Butyrate of glycol $\left(C_{20}H_{18}O_8=\left.\begin{matrix}C_4H_4''\\(C_8H_7O_2)_2\end{matrix}\right\}O_4\right)$ is formed by the action of bromide of ethylene on butyrate of silver in the presence of free butyric acid. The product of the action is treated with ether and the ethereal solution distilled and rectified. Butyrate of glycol is a colourless liquid, with a somewhat butyric odour, boiling at about 464° Fahr. and distilling without alteration. It is quite insoluble in water, but completely so in alcohol and ether.

Stearate of glycol $\left(C_{76}H_{74}O_8=\left.\begin{matrix}C_4H_4''\\(C_{36}H_{35}O_2)_2\end{matrix}\right\}O_4\right)$, obtained by the action of bromide of ethylene on stearate of silver, consists of brilliant small laminæ, fusible at 169° Fahr., and closely resembling stearin.

Benzoate of glycol $\left(C_{32}H_{14}O_8=\left.\begin{matrix}C_4H_4''\\(C_{14}H_5O_2)_2\end{matrix}\right\}O_4\right)$ is prepared like the preceding ethers. It presents the form of colourless, right rhomboidal prisms, which fuse at 153° Fahr., and distil without alteration at a point beyond the ordinary range of the thermometer.

Hydrochloric ethers of glycol. The neutral hydrochloric ether of glycol, and that which stands to glycol in the same relation as chloride of ethyl to alcohol, is the oil of olefiant gas, or chloride of ethylene $C_4H_4Cl_2$. It may be conceived as being derived from glycol by the replacement of 2 eq. of peroxide of hydrogen by 2 eq. chlorine. From the constitution of glycol, it is evident that there may be an ether intermediate between chloride of ethylene and glycol,—in fact glycol in which one eq. of peroxide of hydrogen is replaced by chlorine. The relation of these bodies may be seen from the scheme:—

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H\\H\end{matrix}\right\}O_4}_{\text{Glycol.}} \qquad \underbrace{\left.\begin{matrix}C_4H_4''\\H\\Cl\end{matrix}\right\}O_2}_{\substack{\text{Monochlorhydrate}\\\text{of glycol.}}} \qquad \underbrace{\begin{matrix}C_4H_4''\\Cl_2\end{matrix}}_{\substack{\text{Chloride of}\\\text{ethylene.}}}$$

The body in question has been termed the chlorhydrin of glycol.

It is formed by the action of hydrochloric acid on glycol, and is a colourless liquid, boiling at 262° Fahr. By the action of potash it gives oxide of ethylene.

Chloracetine of glycol $(C_8H_7ClO_4)$. This body is formed by the concurrent action of hydrochloric acid and acetic acid on glycol. It is a colourless liquid, heavier than water, and boiling at 293° Fahr., without decomposition. It is intermediate between chloride of ethylene and acetate of glycol. Its formation may be thus expressed:—

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} + \underbrace{\left.\begin{matrix}C_4H_3O_2\\H\end{matrix}\right\}O_2}_{\text{Acetic acid.}} + HCl = \underbrace{\left.\begin{matrix}C_4H_4''\\(C_4H_3O_2)\\Cl\end{matrix}\right\}O_2}_{\text{Chloracetin of glycol.}} + 4HO$$

It is also formed by the action of hydrochloric acid on monoacetate o glycol.

It is decomposed by potash, with formation of acetate and chloride of potassium.

Chlorbutyrin of glycol and chlorbenzoin of glycol are compounds quite analogous to this, and are prepared by similar methods.

Butyroacetate of glycol. This is glycol in which one atom of hydrogen is replaced by the radical acetyl, and another by butyryl. It is a substance with a bitter pungent taste, heavier than water, and boiling at 410° Fahr. It is formed by the action of chloracetin of glycol on butyrate of silver.

$$\underbrace{\left.\begin{matrix}C_4H_4''\\C_4H_3O_2\\Cl\end{matrix}\right\}O_2}_{\substack{\text{Chloracetin}\\\text{of glycol.}}} + \underbrace{\left.\begin{matrix}C_8H_7O_2\\Ag\end{matrix}\right\}O_2}_{\substack{\text{Butyrate of}\\\text{silver.}}} = \underbrace{\left.\begin{matrix}C_4H_4''\\C_4H_3O_2\\C_8H_7O_2\end{matrix}\right\}O_4}_{\substack{\text{Butyroacetate}\\\text{of glycol.}}} + \underbrace{AgCl}_{\substack{\text{Chloride}\\\text{of silver.}}}$$

It is evident that many such analogous compounds may be formed.

By the action of hydriodic acid on glycol, iodide of ethylene is formed:

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} + \underbrace{2HI}_{\text{Hydriodic acid.}} = \underbrace{\left.\begin{matrix}C_4H_4''\\I_2\end{matrix}\right\}}_{\text{Iodide of ethylene.}} + 4HO$$

By modifying the action of hydriodic acid, an iodhydrin of glycol $\left(\left.\begin{matrix}C_4H_4''\\H\\I\end{matrix}\right\}O_2\right)$, corresponding to the chlorhydrin, appears to be formed. There is also an iodacetin of glycol analogous both in preparation and properties to the chloracetin of glycol.

Sulphoglycolic acid. Sulphuric acid by its action on glycol forms a compound analogous to sulphovinic acid, which has however hitherto only been examined in the baryta salt. Equivalent quantities of glycol and sulphuric acid are mixed together, heated for some time, diluted, neutralised with carbonate of baryta, and evaporated.

Sulphoglycolate of baryta is a somewhat deliquescent salt. Sulphuric acid precipitates sulphate of baryta from its aqueous solution, but baryta water produces no precipitate—at least not in the cold. The formation of sulphoglycolic acid may be thus expressed.

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} + 2SO_4H = \underbrace{\left.\begin{matrix}C_4H_5O_2\\S_2O_4\\H\end{matrix}\right\}O_4}_{\text{Sulphoglycolic acid.}} + 2HO$$

When the acid is neutralised by carbonate of baryta, hydrogen is replaced by barium, and we have the salt, $\left.\begin{matrix}C_4H_5O_2\\S_2O_4\\Ba\end{matrix}\right\}O_4$. Sulphoglycolic acid is monobasic.

Glyoxal and glyoxylic acid.—These are two bodies, the former an aldehyde, and the latter an acid, discovered by Debus, among the products of the oxidation of alcohol by nitric acid. As they belong to the glycol series a brief description of them is here necessary, while for fuller details the reader is referred to Debus' original papers ('Phil. Mag.,' vol. xii. p. 361).

Glyoxal ($C_4H_2O_4$), when pure, is a solid, amorphous, pale-yellowish mass, which deliquesces in the air, and is very soluble in alcohol and ether. It has all the properties of an aldehyde, it reduces silver salts, and forms crystalline compounds with alkaline bisulphites, from which glyoxal is obtained by treatment with dilute acids. The action of ammonia on glyoxal yields two well-defined crystallised bodies, *glycosine* and *glyoxaline*.

Glycosine ($C_{12}H_6N_4$) forms a light white, inodorous, and tasteless white powder, which can be sublimed without change. Its hydrochlorate forms crystals, frequently an inch long. Its platinum salt has the formula, $C_{12}H_6N_4$, 2HCl, $2PtCl_2$. The formation of glycosine from glyoxal and ammonia is analogous to that of amarine from oil of bitter almonds and ammonia, and may be expressed by the equation:—

$$\underbrace{3(C_4H_2O_4)}_{\text{Glyoxal.}} + 4NH_3 = \underbrace{C_{12}H_6N_4}_{\text{Glycosine.}} + 12HO$$

Glyoxaline ($C_6H_4N_2$) crystallises with difficulty; its acid oxalate forms colourless prisms, and its platinum salt, $C_6H_4N_2$, HCl, $PtCl_2$, crystallises in splendid orange-red prisms.

Its formation may be represented by the equation:—

$$\underbrace{2(C_4H_2O_4)}_{\text{Glyoxal.}} + 2NH_3 = \underbrace{C_6H_4N_2}_{\text{Glyoxaline.}} + \underbrace{C_2H_2O_4}_{\text{Formic acid.}} + 4HO$$

Glyoxylic acid, $C_4H_4O_8$, appears on the evaporation of its aqueous solution in vacuo, in the form of a tough, transparent, pale-yellowish syrup, which neither crystallises nor solidifies. Its aqueous solution decomposes carbonates, and saturates strong bases. It is volatile without decomposition. Glyoxylic acid is a monobasic acid. Its salts have the general formula, $C_4H_3MO_8$. They mostly crystallise well.

Glyoxal is the aldehyde of glycol; it is intermediate between glycol and oxalic acid, and occurs among the products of the direct oxidation of glycol. Its analogy to common aldehyde is well seen in the mode of its formation:—

$$\underbrace{C_4H_6O_2}_{\text{Alcohol.}} + 2O = \underbrace{C_4H_4O_2}_{\text{Aldehyde.}} + 2HO$$

$$\underbrace{C_4H_6O_4}_{\text{Glycol.}} + 4O = \underbrace{C_4H_2O_4}_{\text{Glyoxal.}} + 4HO$$

Glyoxylic acid is an intermediate compound between glycolic and oxalic acids, just as oil of bitter almonds is intermediate between benzylic alcohol and benzoic acid:—

$$\underbrace{C_4H_4O_6}_{\text{Glycolic acid.}} \qquad\qquad \underbrace{C_{14}H_8O_2}_{\text{Benzylic alcohol.}}$$

$$\underbrace{C_4H_2O_6}_{\text{Glyoxylic acid.}} \qquad\qquad \underbrace{C_{14}H_6O_2}_{\text{Oil of bitter almonds.}}$$

$$\underbrace{C_4H_2O_8}_{\text{Oxalic acid.}} \qquad\qquad \underbrace{C_{14}H_6O_4}_{\text{Benzoic acid.}}$$

Glyoxylic acid when decomposed by alkalies, splits up into a glycolate and an oxalate; it also readily absorbs oxygen, and passes into oxalic acid. These decompositions are the exact analogues of those which oil of bitter almonds experiences under the same conditions.

These properties and re actions of glycol prove its complete resemblance to alcohol: and it may be expected that to every monobasic alcohol, a biatomic alcohol or glycol will be found to correspond. Besides glycol, three have been already discovered, propylic glycol, butylic glycol, and amylic glycol, corresponding respectively to a monoatomic alcohol:—

$$\underbrace{C_4H_6O_2}_{\text{Alcohol.}} \qquad\qquad \underbrace{C_4H_6O_4}_{\text{Glycol.}}$$

$$\underbrace{C_6H_8O_2}_{\text{Propylic alcohol.}} \qquad\qquad \underbrace{C_6H_8O_4}_{\text{Propylic glycol.}}$$

$$\underbrace{C_8H_{10}O_2}_{\text{Butylic alcohol.}} \qquad\qquad \underbrace{C_8H_{10}O_4}_{\text{Butylic glycol.}}$$

$$\underbrace{C_{10}H_{12}O_2}_{\text{Amylic alcohol.}} \qquad\qquad \underbrace{C_{10}H_{12}O_4}_{\text{Amylic glycol.}}$$

They are derived respectively from propylene, C_6H_6; butylene, C_8H_8; and amylene, $C_{10}H_{10}$; the homologues of olefiant gas. These latter substances, which are true biatomic radicals, by treatment with bromine form biatomic bromides, $C_6H_6''Br_2$, $C_8H_8''Br_2$, and $C_{10}H_{10}''Br_2$, and these bromides, by acting on 2 eq. acetate of silver, yield the acetate of the corresponding glycol, from which, by treatment with potash, the glycol is obtained.

The homologous series of alcohols exhibit a certain regularity in their boiling points. For every increase of C_2H_2 there is an increase of 34° Fahr. in the boiling point. The glycols exhibit a similar but inverse relation. The boiling points have hitherto been determined in most cases in too small quantities of substance to be considered as quite accurate, nevertheless a certain regularity has been observed. The higher a glycol stands in the series, the *lower* are its boiling point and density. Thus:—

		Density.	Boiling Point.
Glycol . . .	$C_4H_6O_4$	1·125	387° Fahr.
Propylic glycol . .	$C_6H_8O_4$	1·051	372° „
Butylic glycol . .	$C_8H_{10}O_4$	1·048	361° „
Amylic glycol . .	$C_{10}H_{12}O_4$	0·987	350° „

To each member of the series of homologous monoatomic alcohols, there is a corresponding acid, a member of the fatty acid series; and similarly there is a homologous series of acids parallel with the glycols, and which are derived from them by direct oxidation:—

$$\underbrace{C_4H_6O_4}_{\text{Glycol.}} + 4O = \underbrace{C_4H_4O_6}_{\text{Glycolic acid.}} + 2HO$$

$$\underbrace{C_6H_8O_4}_{\text{Propylic glycol.}} + 4O = \underbrace{C_6H_6O_6}_{\text{Lactic acid.}} + 2HO$$

$$\underbrace{C_8H_{10}O_4}_{\text{Butylic glycol.}} + 4O = \underbrace{C_8H_8O_6}_{\text{Butylactic acid.}} + 2HO$$

The acid corresponding to amylic glycol has not been discovered. On the other hand, leucic acid ($C_{12}H_{12}O_6$), which has long been recognised as a homologue of lactic acid, probably corresponds to a glycol hitherto undiscovered, caprylic glycol, $C_{12}H_{14}O_4$.

The acetate of methylic glycol has been prepared from iodide of methylene, $C_2H_2''I_2$. It has the formula $\left.\begin{matrix}C_2H_2''\\(C_4H_3O_2)^2\end{matrix}\right\}O_4$. It has not been possible to obtain from it methylic glycol, as by treatment with bases it is completely decomposed.

A series of bodies has been obtained by Wicke, which are considered to be derivatives of a glycol of the benzoic acid series. By the action of chlorobenzole ($C_{14}H_6''Cl_2$) on acetate of silver, a substance is obtained which has the formula $\left.\begin{matrix}C_{14}H_6''\\(C_4H_3O_2)^2\end{matrix}\right\}O_4$. This would be the formula of the acetate of a glycol, $C_{14}H_8O_4$, corresponding to benzöylic alcohol ($C_{14}H_8O_2$). But Wicke has not been able to prepare the glycol itself, from the tendency the compound has of producing benzoic aldehyde when decomposed by bases. The body exhibits in several instances re-actions, deviating from those of the ordinary glycols, and until the subject has been further examined, it cannot be considered as the derivative of a true glycol. A similar compound has been obtained from the cumol series.

The further study of the glycols and their derivatives may be expected to throw light on many bodies whose relations are at present obscure or unknown. Probably meconin and saligenin will be found to be biatomic alcohols. Berthelot has obtained a combination of stearic acid with meconin, which has the formula :—

$$\left.\begin{matrix}(C_{20}H_8O_4)''\\(C_{36}H_{35}O_2)^2\end{matrix}\right\}O_4$$

And saligenin, $C_{14}H_8O_4$, appears to be the glycol corresponding to salicylic acid, $\left.\begin{matrix}C_{14}H_6''\\H_2\end{matrix}\right\}O_4$.

GLYCOLIC ACID ($C_4H_4O_6$). This acid is the lowest member of the series of acids to which *lactic* and *leucic acids* belong, and recent researches have established a close relation between it and glycol.

It is formed by a variety of processes. It was first obtained by the action of nitrous acid on glycocoll. An aqueous solution of glycocoll is saturated with nitrous acid, and the solution extracted with ether; on the evaporation of the ethereal solution, the acid is left in the form of a thick syrup. The action is analogous to that by which alanin, the homologue of glycocoll, is converted into lactic acid :—

$$\underbrace{C_4H_5NO_4}_{\text{Glycocoll.}} + \underbrace{NO_3}_{\text{Nitrous acid.}} = \underbrace{C_4H_4O_6}_{\text{Glycolic acid.}} + 2N + HO$$

Glycolic acid also occurs among the products of the oxidation of alcohol by nitric acid. It is also formed by the oxidation of glycol.

Another mode of its formation also shows its relation to lactic acid. When tartraric acid ($C_6H_4O_{10}$), an acid produced by the spontaneous decomposition of nitrotartaric acid, is heated, it decomposes into water, carbonic acid, and *glycollide* :—

$$\underbrace{C_6H_4O_{10}}_{\text{Tartraric acid.}} = \underbrace{C_4H_2O_4}_{\text{Glycollide.}} + 2HO + 2CO_2$$

Glycollide stands to glycolic acid in the same relation as lactide to lactic acid: it is the anhydride of glycolic acid. When it is digested for some time in the warm with water, it assimilates 2 eq. of water, and becomes converted into glycolic acid.

Perhaps the best method of preparing glycolic acid is by the spontaneous decomposition of chloracetic acid. When an aqueous solution of chloracetate of potash is heated in a closed vessel to between 250° and 280° Fahr., chloride of potassium is formed, and the solution contains glycolic acid :—

$$\underbrace{C_4H_2ClKO_4}_{\text{Chloracetate of potash.}} + 2HO = \underbrace{C_4H_4O_6}_{\text{Glycolic acid.}} + \underbrace{KCl}_{\text{Chloride of potassium.}}$$

Glycolic acid, in its state of greatest concentration, has the form of a thick syrup, which, dried in vacuo over sulphuric acid, forms long well-defined crystals. It is miscible with water, alcohol, and ether, in all proportions. Its aqueous solution decomposes carbonates. The zinc salt has the formula $C_4H_3ZnO_6 + 2$ aq., and greatly resembles the corresponding lactate of zinc. When glycolic acid is mixed with acetate of lead, and excess of ammonia added, a white precipitate is formed. By this deportment it is distinguished from lactic acid, which, under the same circumstances, remains clear. *Glycolate of lime* ($C_4H_3CaO_6$) crystallises from a hot aqueous solution in stellate groups of very fine asbestos-like needles. It is quite insoluble in alcohol, even when dilute, and is hence easily separated from lactate of lime, which is soluble.

Glycolic acid stands in the same relation to glycol as acetic acid to alcohol. Both acids are derived from their corresponding alcohols by direct oxidation :—

$$\underbrace{C_4H_6O_2}_{\text{Alcohol.}} + O_4 = \underbrace{C_4H_4O_4}_{\text{Acetic acid.}} + 2HO$$

$$\underbrace{C_4H_6O_4}_{\text{Glycol.}} + O_4 = \underbrace{C_4H_4O_6}_{\text{Glycolic acid.}} + 2HO$$

When the oxidation of glycol is more energetic, oxalic acid is formed. These two acids represent, in a certain sense, the degrees of oxidation of glycol. Thus—

$$\underbrace{\left.\begin{matrix}C_4H_4''\\H_2\end{matrix}\right\}O_4}_{\text{Glycol.}} \qquad \underbrace{\left.\begin{matrix}C_4H_2O_2''\\H_2\end{matrix}\right\}O_4}_{\text{Glycolic acid.}} \qquad \underbrace{\left.\begin{matrix}C_4O_4''\\H_2\end{matrix}\right\}O_4}_{\text{Oxalic acid.}}$$

In accordance with this view, glycolic acid must be bibasic. Hitherto only monobasic salts have been formed. Its homologue, however, lactic acid (which is a derivative of propylglycol, the homologue of glycol), is bibasic, and it is to be expected that further researches will establish the bibasicity of glycolic acid. [GLYCOL.]

GLYCOLLAMIDE. [GLYCOLLIDE.]

GLYCOLLIDE ($C_4H_2O_4$). This body stands in the same relation to glycollic acid as lactide does to lactic acid, and is formed by the action of heat upon tartronic acid :—

$$\underbrace{C_6H_4O_{10}}_{\text{Tartronic acid.}} = C_2O_4 + \underbrace{C_4H_2O_4}_{\text{Glycollide.}} + 2HO$$

It is a white tasteless powder, insoluble in cold water, and very slightly so in hot. Treated with ammonia, it is transformed into *glycollamide* :—

$$\underbrace{C_4H_2O_4}_{\text{Glycollide.}} + NH_3 = \underbrace{C_4H_5NO_4}_{\text{Glycollamide.}}$$

Glycollamide forms fine colourless crystals, very soluble in water, sparingly soluble in alcohol, and possessing a slightly sweet taste. It is isomeric with sugar of gelatin.

GLYCOCHOLALIC ACID. [CHOLIC ACID.]

GLYCOCHOLIC ACID. [CHOLIC ACID.]

GLYCOSINE. [GLYCOL, *Glycosine.*]

GLYCYL ($C_6H_5O_2$). A hypothetical radical, supposed to be contained in GLYCERIN, whose formula then becomes $\left.\begin{matrix}C_6H_5O_3\\H\end{matrix}\right\}O_2 + \left.\begin{matrix}H\\H\end{matrix}\right\}O_2$.

GLYCYRHIZA GLABRA, and *G. echinata*, liquorice, of which the root, or rather the rhizoma, and a watery extract are officinal. These are natives of Germany and south of Europe, but cultivated extensively in some parts of Britain; the extract is however chiefly prepared in Spain, Italy, and Sicily, and imported under the name of Spanish juice or liquorice: the finest is called Solazzi. The rhizoma is generally allowed to attain the age of three years, and is then taken up. It is often several feet in length, and about half an inch thick. The odour is faint, the taste sweet but mawkish; and if the bark be chewed, it is at last rather acrid, which is owing to the presence of a soft resin, or oleo-resin.

Robiquet found it to contain a peculiar sugar, which is uncrystallisable and unfermentable, called *glycion*, or *glycyrhizin*, and other matters.

Infused in warm, or macerated in cold water, it affords a mucilaginous fluid, which is bland and demulcent. The powder is much used to involve recently made pills, in order to prevent them from adhering to each other. Before using it for an infusion, or to powder it, the bark should be removed, by which the bitterness is avoided.

The extract is formed into rolls from 6 to 8 inches long, which are dried, and surrounded with bay leaves, to prevent them from adhering, as in warm weather they have a tendency to melt, notwithstanding the addition to them of starch or peas-meal: 100 lbs. of the dried root yield 30 lbs. of extract.

Good liquorice juice is black, dry, easily broken (in cold weather), with a shining fracture. It should dissolve easily and entirely in the mouth when pure; but crude liquorice, besides starch or meal, has generally more or less copper, rarely brass, derived from the pans in which it has been boiled; it is therefore subjected to a process of purification, and is then termed *refined* liquorice. This is done by melting it in water, draining off the solution, so as to leave the sand and other impurities behind, and inspissating it; then forming it into more slender cylinders, which are generally soft and moist, even when sugar has been added to them: a better addition is a small quantity of gum arabic. In Yorkshire an extract is prepared which is sold under the name of Pontefract cakes.

Both the crude Spanish and refined liquorice are used as demulcents, to allay tickling cough in slight cases of catarrh: often formed into lozenges, plain or medicated. The *Trochisci glycyrrhizæ cum opio* avowedly contain opium, but too many of the nostrums sold as cough lozenges contain *morphia* to a considerable extent, and are therefore dangerous when too freely used.

GLYCYRRHIZIN ($C_{16}H_{12}O_6$, or $C_{36}H_{24}O_{14}$). An unfermentescible saccharine matter contained in liquorice root. It is a brown translucent amorphous substance, only slightly soluble in cold water, and possessing a nauseous, saccharine, but slightly bitter, taste. Its hot solutions gelatinise on cooling.

GLYOXALINE. [GLYCOL, *Glyoxaline.*]

GLYOXYLIC ACID. [GLYCOL, *Glyoxylic acid.*]

GLYPTOGRAPHY. [ELECTRO-METALLURGY.]

GNOMIC POETS OF GREECE. Under this title are included those moral and philosophical poets whose remains consist chiefly of short sententious precepts or reflections. Such are the Gnomæ of Theognis, which, though numbered consecutively as a connected poem to 1200 lines, form in fact a collection of unconnected members, varying from two to thirty lines in length. Such also were the sentences inscribed by Hipparchus on the Hermæ in the streets of Athens. These metrical precepts were valuable before writing became common; being, like proverbs, serviceable and easily-remembered rules of conduct. This notion of a pithy saying, or apophthegm, is one of the meanings of *γνώμη* (gnóme), whence comes the adjective γνωμικός (gnomikos), relating to gnóme. Winterton's 'Poetæ Minores Græci' (Cambridge, 1677, and later editions) contains a collection of the Gnomic poets. They have also been edited by Brunck ('Gnomici Poetæ Græci,' Argent., 1784, 4to.). The principal authors contained in this edition are Theognis, Tyrtæus, Solon, Simonides, with many others, some to the extent only of a few lines. Tyrtæus and Simonides, however, though the authors of Gnomæ, hardly come under the definition above given, or under any other definition which accurately characterises Theognis and others. Brunck's edition contains also a collection of Gnomæ from the comic writers.

The Gnomic writers are sometimes all classed under the general name of Elegiac poets. [ELEGY.]

GNOMON (the Greek *γνώμων*), or style of a dial, is the plate which projects from the surface of the dial-plate, the edge of its shade determining the hour-line. The plates now in use being flat, the gnomon is in the plane of the meridian, and its sloping edge forms an angle with the horizon equal to the latitude of the place, and is consequently parallel to the axis of the earth. No sensible error is made by confounding the edge of the gnomon with the earth's axis; but in lunar dials a sensible error would arise, except in places of which the latitude is nearly 90°: this error, in either case, depends upon the parallax of the luminous body, and the position of the dial-plate. The ancients, who used hemispherical dial-plates, placed the radius which threw the shade in the direction of the north pole-star, and therefore the hour-lines were circular arcs, at regular intervals of 15°. Herodotus says (ii. 109) that the Greeks borrowed the gnomon and the sphere (*πολος*) from the Babylonians.

The science of gnomonics, upon which many formal treatises have been written, has declined as the theory of astronomy has advanced towards correctness. In the succeeding article one method of construction of a dial will be briefly explained. It is not worth while to enter upon the details of constructions which are now of no use. A sun-dial may be sufficiently well adjusted to give the time within a few minutes, provided the observer has an almanac, or some other work in which the equation of time is contained, by which the indications of the sun are made to agree with those of the clock. [SUN; SUN-DIAL.]

GNOMONIC PROJECTION. The gnomonic projection of any portion of a sphere is that which is constructed on the supposition that the eye is in the centre of the sphere. The consequence is, that any great circle whatsoever of the sphere is projected into a straight line; which property can belong to no other projection.

The most convenient method of projecting the whole sphere gnomonically is to imagine a cube inscribed about it, on each face of which one-sixth part of the sphere is projected, by lines drawn through the centre. The maps of the earth and of the stars published by the Society for the Diffusion of Useful Knowledge are drawn in this manner, a full account of which may be found in the 'Explanation of the Maps of the Stars' (Baldwin, 1836). The result is six maps, which embrace the whole sphere; the shortest distance from any one point to another on the sphere being projected into the shortest distance between their corresponding points on the map, when they lie on the same map.

The gnomonic projection derives its name from the connection between the methods of describing it and those for the construction of a gnomon or dial. The direction in which the shadow of a line parallel to the axis of the earth will be thrown is the intersection of the hour circle for the time being with the surface of the dial (whether plane or not). Imagine a sphere, and the surface of the dial drawn through its centre. Upon this sphere describe the heavens, and project the whole upon a circumscribed cube. Nothing is more easy than to draw the hour circle upon such a projection, and if the intersection of the surface of the dial with the cube be traced out upon the cube, the points at which the projections of the hour circles meet the intersection of the cube and the dial are those towards which the shadow of the axis will point at the hour in question. When a dial is to be constructed geometrically, this is the most simple plan: but calculation, as in other instances, is superior to construction for purposes of accuracy.

GNOSTICS, derived from the Greek word *gnōsis* (*γνώσις*), "knowledge," was employed by the fathers of the first two centuries as a generic term to designate all individuals who professed to interpret the Scriptures by the aid of philosophy. It is supposed from various passages in the New Testament (Col. ii. 8; 1 Tim. i. 4; vi. 20; 2 Tim. ii. 16, 17; Titus, iii. 9; 1 John, ii. 18) that the doctrines of the Gnostics were taught in the times of the Apostles; and the Nicolaitans, who are condemned by St. John (Rev. ii. 6, 15), are looked upon by the fathers as forming a sect of the Gnostics. Many of the fathers considered Simon Magus, Dositheus, and Menander to be the first individuals who propagated Gnostic opinions; but they are more correctly classed by others among the opponents rather than the corrupters of Christianity. The principal teachers of Gnosticism were Saturninus, Basilides, Cerinthus, Carpocrates, and Prodicus, of whom the most celebrated were Cerinthus and Carpocrates; and some of their tenets were held on the authority of passages in the apocryphal gospels of the New Testament. Irenæus ('Adv. Hæres.' iii. 11) states that St. John wrote his gospel in order to refute the errors of Cerinthus; but many critics reject this testimony of Irenæus, and maintain that Cerinthus lived in the second century. The Ebionites also [EBIONITES] are supposed to have been Gnostics.

The origin of the Gnostic system has been traced to various sources. Some have derived their doctrines from the Alexandrian school of philosophy; others from the Jewish Cabbala [CABBALA]; and a still greater number from the Oriental belief in two great independent principles, one the author of good, and the other of evil. Many parts of the Gnostic system may be alleged in favour of each of these suppositions; but it seems to be forgotten that Gnosticism is merely a generic term, and that it included many sects that differed considerably from each other: we should therefore regard it rather as derived from all these ancient systems than formed from any one in particular. For the reasons that have already been mentioned, it is difficult to give an account of their opinions that will apply equally to all the sects into which the Gnostics were divided; but the following abstract contains the doctrines which were regarded by the fathers as characteristic of Gnosticism.

One of the chief sections considered it beneath the might of the Supreme Deity to labour, and therefore maintained that God could not have created the world. They believed that God dwelt in a *plērōma* (*πλήρωμα*) of inaccessible light, and that he was unknown to the world before the coming of Christ; that he created two other beings, called *Æons*, or emanations; that from these other Æons were descended, at the head of whom was one named *Demiurgus*, who created the world; that this Demiurgus was the God of the Old Testament; that Christ, who was one of the Æons, was sent into the world to restore men to the *gnosis* (knowledge) of the true God; that the Æon Christ descended into the man Jesus at his baptism, and left him when he was led to crucifixion, so that the man Jesus alone suffered. This was in effect the belief of the Gnostics of the Jewish Alexandrian school. Another branch, probably of previous oriental converts opposed to Judaism, maintained that the Demiurgus was entirely antagonistic to the Supreme Deity, and that this was shown in the Old Testament; that all matter was intrinsically evil; that the incarnation of Christ was undertaken to relieve mankind from this position; and that an individual at his death was raised to inhabit the divine pleroma, into which corruptible and sinful matter could not enter.

Their doctrines are said to have produced very opposite effects upon their moral conduct; some, looking upon the body as sinful, mortified it by severe penances; while others, with the same opinion, led immoral lives, maintaining that the soul could not be affected by the acts of the body.

(Neander, *Kirchengeschichte*; Mosheim, *Ecclesiastical History*; Lardner's *History of Heretics*; Möhler, *Versuch über den Ursprung der Gnostiker*, 1831; Baur, *Die Christlichen Gnosis in geschichtliche Entwickclung*, 1835.)

GOITRE. [BRONCHOCELE.]

GOLD (Au) is a metal which has been known from the remotest antiquity, and has been universally employed as a medium of exchange. Although the quantity of gold which is found, when compared with that of other metals, is small, yet it occurs in greater or less abundance in almost every part of the globe. It occurs in the native state, and alloyed with silver, also occasionally combined with tellurium, and frequently mixed with metallic sulphurets and arseniurets. It is indeed stated by Gahn that but little sulphuret of iron is met with which does not contain some gold. A large quantity of gold is obtained from South America; the richest mines of Europe are those in Hungary; it has been found also in the sand of the Rhône, the Rhine, and the Danube; small quantities are occasionally found in the stream tin-works of Cornwall; and in Wicklow in Ireland, and the lead-hills of Scotland, no inconsiderable portions have been from time to time collected. But by far the largest supplies of this metal are now derived from Australia and California. Gold is also met with in tolerably large quantity in the Uralian mountains of Siberia.

Native gold occurs crystallised, capillary, and massive; the primary form is a cube. It gives no cleavage; fracture hackly; hardness 2·5 to 3·0; colour yellow, of various shades; streak shining, opaque; specific gravity 17 to 19.

Gold not unfrequently occurs alloyed with silver, and this compound, where the quantity of silver is considerable, is known by the name of *electrum*. Electrum analysed by Klaproth was found to consist of 64 of gold and 36 of silver, which are almost exactly in the proportions of one equivalent of each metal. Boussingault, who has since examined electrum from various parts of Columbia, found it to consist of very different proportions of the metals, but they were all definite compounds. Gold is separated from the various substances with which it is mixed by the process of amalgamation; this consists in combining it with mercury, and heating the amalgam formed, so as to distil the mercury, which is thus repeatedly used for the same purpose.

Gold is of a fine yellow colour, and is susceptible of a high degree of polish. It is nearly as soft as lead; its specific gravity is 19·3; it is so exceedingly malleable that one grain may be extended over fifty six square inches of surface, and gold leaf is only about $\frac{1}{200000}$ of an inch in thickness; some authors say $\frac{1}{282000}$ of an inch. Gold is also exceedingly ductile; a single grain may be drawn out into 500 feet of wire: in point of tenacity it is inferior to iron, copper, platinum, and silver; a wire 0·787 of a line in diameter is capable of supporting about 150 pounds. Gold suffers no change by exposure to air or moisture, even when heated. It melts at about 2016° Fahr., according to Daniell's pyrometer; when in fusion it appears of a brilliant green colour. It is scarcely at all volatile, and may be long kept in fusion in a furnace without losing weight; but when it is melted by the heat of a lens a plate of silver held over it at some inches distance becomes gilt by its vapour. It contracts more than any other metal on cooling, and crystallises in octohedrons.

We shall now describe the more important compounds of gold. Oxygen and gold unite, but not by direct action; it has indeed been stated that gold may be oxidised by the electric spark in atmospheric air, but this is denied by Berzelius.

Oxide, or Protoxide, of Gold (AuO) is prepared by adding a solution of potash to one of protochloride of gold; a green powder is separated, which is the protoxide in question; it must be washed and dried at a temperature not exceeding 100° Fahr.; if the heat exceed this it is converted into metallic gold and peroxide; indeed, this change is stated by some authors to occur at almost any temperature; it is, at any rate, an extremely unstable compound.

Peroxide, or Teroxide, of Gold (AuO_3) is best obtained, according to Pelletier, by decomposing solution of perchloride of gold by digesting it with a slight excess of magnesia; the peroxide of gold precipitates in combination with the magnesia; after being washed the precipitate is treated with dilute nitric acid, which dissolves the magnesia and a little of the peroxide of gold, but leaves the greater part unacted upon; it is a hydrate, of a bright reddish-yellow colour; but when concentrated nitric acid is used instead of dilute, the oxide is anhydrous, and nearly black. This oxide is decomposed by exposure to daylight, its oxygen being expelled. This oxide is with difficulty soluble in any acid; thus, although sulphuric acid dissolves a small portion, it is precipitated by water. It appears indeed to possess rather the powers of an acid than a base, and has been called *auric acid*, and it combines with potash, soda, and baryta, to form salts, which have been termed *aurates*.

Neither nitrogen nor hydrogen combines with gold.

Chlorine and Gold unite to form two compounds. The perchloride is most readily obtained; it may be formed by treating gold with nascent chlorine, derived from the mutual decomposition of nitric and hydrochloric acids, called *aqua regia*.

Perchloride, or Terchloride, of Gold ($AuCl_3$) gives a yellow-coloured solution, which becomes nearly red by evaporation, owing to concentration and the expulsion of any excess of acid. Its taste is acrid and bitter; with excess of acid this salt crystallises in long needle-form crystals of a bright yellow colour, which are unalterable in a dry atmosphere, but deliquesce in a moist one; on the contrary, when a neutral solution is evaporated until chlorine commences to be evolved, a deep ruby-coloured crystalline mass of perchloride of gold is obtained. Gold is precipitated in the metallic state from the perchloride even by the action of light; hydrogen, charcoal, phosphorus, and many metals, produce a similar effect; so also do the protosulphate of iron, &c. The skin is stained of a purple colour by this solution.

Protochloride of Gold ($AuCl$) is obtained by heating the perchloride to a temperature of about 350° Fahr. in a porcelain vessel. If it be too strongly heated, gold is deposited; it is better therefore to heat it rather less, and to treat the residue with water, which dissolves the perchloride and leaves the protochloride, which is a colourless saline mass, unalterable in the air, but in contact with water gradually changes into metallic gold and perchloride: boiling water decomposes it instantly.

Terbromide of Gold ($AuBr_3$) is procured by dissolving the metal in a mixture of hydrobromic and nitric acids. The solution yields by evaporation a deep red-coloured saline mass; sometimes it yields crystals. This salt has so intense a colour that one part of it tinges 5000 parts of water.

Sulphuret of Gold (AuS_3) is prepared by passing hydrosulphuric acid gas into a solution of perchloride of gold; it is a black powder, which, when heated, readily separates into sulphur and gold. This sulphuret is soluble in the alkalies potash and soda, and prepared in a different mode it is employed in gilding porcelain vessels.

Phosphuret of Gold may be obtained either by directly heating gold-leaf and phosphorus in a tube deprived of air, or by passing phosphuretted hydrogen gas into a solution of chloride of gold. As obtained by the first process it is a gray substance of a metallic lustre; when obtained by the second it is a brownish powder. When heated in the air it is decomposed. Its composition has not been determined.

Teriodide of Gold (AuI_3). Iodine and gold do not act upon each other even when heated together; but when a solution of iodide of potassium is mixed with one of perchloride of gold, yellowish brown iodide of gold is precipitated, which is insoluble in cold water, dissolved by the alkaline solutions, and decomposed by heat.

Having described the principal binary compounds which result from the union of gold with non-metallic elements, we shall mention the more important compounds which it forms with the metals.

Alloys of Gold.—Most metals are susceptible of combining with gold; but it is to be observed that nothing is known of the compounds which it forms with the metals of the alkalies and earths, as potassium, calcium, &c.

Arsenic and Gold.—This alloy is obtained by heating gold-leaf and arsenic; with the application of a gentle heat the vaporised arsenic combines with the gold; it is a very brittle, gray, metallic compound, it is readily decomposed by calcination, and the whole of the arsenic is expelled; $\frac{1}{600}$ of arsenic is sufficient to destroy the malleability of gold without altering its appearance; $\frac{1}{240}$ renders it gray and brittle.

Tellurium and Gold, but mixed also with a considerable portion of lead, occur in combination, constituting three varieties known as—*graphic tellurium, yellow tellurium,* and *black tellurium.*

Antimony and Gold.—According to Hatchett, gold loses its ductility by combining with $\frac{1}{1920}$ of its weight of antimony. It is prepared by fusing the metals together; it is of a pale colour and fine grained; when long calcined in an open crucible the antimony is entirely expelled.

Manganese and Gold.—This alloy is of a pale colour; breaks readily under the hammer, and exhibits a spongy coarse-grained fracture.

Zinc and Gold yield an alloy of a pale greenish colour like brass, and totally devoid of ductility.

Tin and Gold.—Colour very pale whitish-yellow; bends readily when the bar is not more than one-eighth of an inch thick; but when passed between rollers breaks longitudinally into several pieces. The grain of the fracture is fine, inclining to an earthy appearance, and is of a pale yellowish-gray colour.

Iron and Gold form an alloy of a pale yellowish-gray colour; it is very ductile, and may be rolled from the thickness of three-quarters of an inch to that of a guinea.

Nickel and Gold.—This alloy is of a fine brass colour; it immediately breaks under the hammer, with a coarse-grained earthy fracture.

Cobalt and Gold.—A pale yellow alloy mixed with gray; it is brittle, and has a fine-grained earthy fracture.

Copper and Gold combine in all proportions, without altering the colour of the gold; the density is diminished, but the hardness is increased. The alloy employed for ordinary jewellery contains 23·6 per cent. of copper; this tarnishes by use, owing to the oxidisement of the copper; the original colour is restored by treating with ammonia. Copper is used to alloy the gold of coin, in order that it may be rendered sufficiently hard to stand the wear to which it is exposed; the amount of copper is 1 in 12. Its specific gravity is 17·157. Of this alloy, 20 troy pounds are coined into 934 sovereigns and one half-sovereign.

Bismuth and Gold form a very brittle alloy. It is sufficient to alloy gold with $\frac{1}{1920}$ of bismuth to render it brittle. A compound of 8 bismuth and 92 gold is of a pale yellow colour and brittle.

Silver and Gold combine well; the resulting alloys are very ductile. A small quantity of silver renders gold pale; 5 parts to 100 are sufficient for this effect. This compound was used by the ancients, and called by them *electrum*; we have already mentioned the existence of several native alloys of these metals, and that they are always combined in definite proportions.

Lead and Gold.—This alloy is very brittle, even when the lead forms only $\frac{1}{1920}$ of the alloy; even the fumes of lead destroy the ductility of gold.

Mercury and Gold combine with great facility, and yield a white alloy, usually called an *amalgam*, much used in gilding. [GILDING.] On account of the readiness with which these metals unite, mercury is used, as already noticed, for separating gold in the process called amalgamation.

Platinum and Gold combine in all proportions; these alloys are fusible. Platinum readily destroys the colour of the gold; the presence of only 0·02 of platinum is recognised by the extraction of colour.

Salts of Gold, in which the oxide is a base, are obtained with great difficulty; indeed, when the peroxide is dissolved in nitric, acetic, or sulphuric acid, they require to be concentrated, the oxide does not saturate the acids, and the solutions are all decomposed by water.

Salts of gold in which the peroxide acts as an acid do not, except one of them, possess any remarkable properties; this peroxide of gold is soluble in potash and soda, but no very definite or crystallised compounds of them have been formed. Ammoniuret of gold, sometimes called aurate of ammonia, is formed when ammonia is added to a solution of perchloride of gold; water is decomposed, and peroxide of gold precipitated in combination with a portion of the ammonia. This substance is of a yellowish-brown colour; it is to be collected in a filter, washed with a little water, and dried at a temperature below 212°. When this substance is heated it explodes violently, the gold is reduced to the metallic state, water is formed by the union of the oxygen of the oxide of gold with the hydrogen of the ammonia, and azotic gas is given out. It probably consists of two equivalents of ammonia and one equivalent of peroxide of gold; it may, however, possibly be a nitride of gold.

Some of the most permanent salts of gold are the double chlorides: thus the potassio-chloride of gold crystallises in small hexagonal tables; it is, however, quickly efflorescent in the air. The sodio-chloride of gold crystallises in long quadrilateral prisms which are not altered by exposure to the air. When heated it melts in its water of crystallisation, and afterwards loses a little chlorine. It appears to be the most stable of all the salts of gold. It consists of 14·68 parts of chloride of sodium, 76·32 of perchloride of gold, and 9 of water. The chloride of ammonium, the chloride of lithium, barium, &c., form crystalline double salts with the chloride of gold.

There is a compound containing gold which has been long used for giving a red colour to glass, under the name of the *purple powder of Cassius.* According to Berzelius, it is composed of 28·35 of gold, 64 of peroxide of tin, and 7·65 of water. Other chemists have assigned a different constitution to this substance. It is of a fine purple colour, and may be prepared by adding a solution of perchloride of gold to a mixed solution of protochloride and perchloride of tin, or simply by putting tin-foil into a solution of gold.

The general properties of the solutions of gold are, protosulphate of iron precipitates metallic gold from the chloride; protonitrate of mercury gives a black precipitate, and so does the protochloride of tin; but a mixture of the proto- and per-chloride, as already noticed, gives a purple precipitate. Hydrosulphuric acid throws down black sulphuret of gold; ammonia, as already noticed, throws down a yellowish-brown precipitate of fulminating gold, which an excess of the alkali re-dissolves. Many of the metals, phosphorus, and charcoal, precipitate metallic gold, as also do oxalic acid and tartrate of potash, when heated.

GOLD-BEATERS' SKIN. The preparation of the delicate membrane known by this name forms part of an exceedingly dirty and disagreeable class of manufactures called by the French "boyauderie," from the word "boyau," intestine. The strings for violins, harps, and guitars [Catgut Strings], gold-beaters' skin, and some other valuable articles of a membranous character, are made from the intestines of animals—not (except in a few cases) from the whole thickness of the intestine, but from a very thin membrane which covers it either on the interior or the exterior. It is from the large intestine of the ox that gold-beaters' skin is prepared. This intestine is composed of three coats or sheathings; the mucous membrane on the inside, the peritoneal membrane on the outside, and the muscular membrane between them. The peritoneal membrane is the one required for the purpose. In the first place, the intestine is freed from all greasiness by soaking, scraping, and washing; it is then turned inside out, and put into a tub. The tub contains a strong alkaline liquor, in which the intestine is allowed to steep for several hours; and at the expiration of that time the mucous membrane has become so far loosened as to be easily removed. The alkaline liquor employed, called "eau-de-Javelle," removes all trace of fetid odour. The peritoneal membrane is afterwards carefully removed, and stretched out to dry. It is next steeped in a weak solution of potash, and carefully scraped. After this it is stretched out on a frame, with that surface undermost which had adhered to the muscular membrane; another membrane, placed the contrary way uppermost, is laid upon it, and the two are easily made to unite firmly. The membrane is then moistened successively with different liquids, of which one is a solution of alum, one a solution of isinglass, and another a layer of white of egg. Beating, drying, and pressing are also among the processes to which the membrane is subjected; each manufacturer appearing to have his own peculiar mode of proceeding.

A packet of skins properly prepared for gold-beating is rather a costly piece of apparatus; but it will bear a surprising amount of beating without injury. The skins may be used for several months without become thinner or weaker. They acquire, however, by degrees a greasiness of surface which temporarily unfits them for their office; this greasiness is removed by interleaving them with pieces of clean white paper, and hammering them for a considerable time, whereby the greasiness is removed from the skin to the paper.

The unhealthiness of this manufacture has been deemed in France so serious as to engage the attention both of medical men and of the legislature. M. Parent Duchâtelet states that the odour arising from the putrefactive fermentation of the substances used, is more loathsome than any other process incident to manufactures; and that the effect of the exhalation on the health of the inhabitants who lived near the boyauderies was such as to lead the French government, towards the end of the last century, to prevent the boyaudiers from continuing to carry on the manufacture in the faubourg where they had congregated, and where a street was named after them, the Rue de la Boyauderie. They left that spot, and established themselves near Montfauçon; but here they formed a new centre for disease and infection. At length, in or about 1820, the Council of Health offered a prize for the discovery of any mode for separating the peritoneal membrane without subjecting the intestine to the putrefactive action. M. Labarreque obtained the prize, by showing how chlorine could be employed both to fumigate the workshops, and to loosen the membranes one from another without allowing the offensive odour to escape. In 1810 the different manufactories of France were ranged in classes according to the unhealthiness of the employments; and the boyauderies were placed at the head of the list of "Etablissements Insalubres:" they were subjected to rather strict regulations in relation to the position and general arrangements of the buildings; and these rules are still acted on in cases where the new method is not adopted.

This manufacture is also carried on in England. Before the removal of the cattle market from Smithfield to Pentonville, and the pulling down of houses to form Victoria Street, most of the English workers in this disagreeable trade congregated in and near Cow Cross. A *mould*, or group of 800 pieces of gold-beaters' skin, is valued at no less than 10*l.*, for gold-beating purposes.

GOLD BEATING. This is a process whereby gold is brought to the state of very fine leaves, for use in various kinds of gilding. The remarkable ductility of gold—a quality possessed by it in a greater degree than by any other known substance—is here taken advantage of to the fullest extent, as a means of limiting the quantity of this costly material required in gilding. So far is the attenuation carried, that a hundred square inches of nearly pure gold can be purchased for about sixpence.

It is by a combined process of rolling and hammering that the attenuation of the gold is produced. The metal is melted in a small crucible by the heat of a wind furnace; and is cast into an iron ingot-mould, so as to form an oblong flat bar about three quarters of an inch in width, and weighing two ounces: a little borax is used to facilitate the melting of the gold, and the ingot mould is greased on the inside to prevent the adhesion of the gold to it. The ingot, when removed from the mould, is immersed in hot ashes, whereby the gold is both annealed and freed from grease. When cold, it is ready to undergo the process of reduction in thickness, and proportionate extension in length and breadth. Formerly, in France, the ingot was beaten out to the state of a thin riband, by the use of a forging-hammer about three pounds weight; but the French gold-beaters now carry this hammering only to such an extent as to reduce the ingot to the state of a plate about one-sixth of an inch in thickness, and then finish by the use of the rolling, flatting, or laminating mill. In England this forging is dispensed with, and the reduction of the gold to the state of a riband is effected by means of the mill. This mill consists of two rollers made of polished steel, perfectly cylindrical in form, and adjusted with very great nicety; it must so act as to reduce the gold equally in every part, or else the further thinning could not be properly carried on. The milling is continued until the ingot of two ounces is spread out to a surface of 960 square inches, with a thickness of rather more than 1-800th of an inch.

This thin riband of gold is then consigned to the hands of the gold-beater. The hammering does not take place on the gold itself; but thin membranes are interposed between the hammer and the gold. These membranes are of three kinds: an outside covering of common parchment; a set of leaves made of very fine and smooth calf-skin vellum; and another set made of the gold-beaters' skin described in the last article. The riband of gold is cut up into small pieces, each measuring exactly an inch square; and a hundred and fifty of these are interleaved with an equal number of leaves of vellum, about four inches square; each piece of gold being placed on the middle of a leaf of vellum. Over this packet of vellum-leaves is drawn a parchment case, open at both ends; and over this another parchment case at right angles to the former; so that the vellum and gold are enclosed tightly on all sides. The entire packet thus prepared is beaten. This beating is effected on a smooth block of marble, strongly imbedded beneath, and bounded on three sides by a raised ledge of oak wood; the front edge is open, and has a leathern flap attached to it, which serves as a kind of apron for catching fragments of gold that may fall off in the subsequent operations. The hammers employed are very ponderous, weighing about sixteen, twelve, and ten pounds respectively; the heaviest is used first, and the others are brought into use as the gold becomes thinner.

The packet of interleaved vellum and gold is laid on the stone, and the workman beats with regular and heavy blows, on the middle of the upper side; there is a spring or elasticity of the packet which enables the hammer to rise easily after each blow; otherwise the work would be too laborious for any man continuously. The beater turns the packet over from time to time, to equalise the action among the leaves; and he occasionally bends the packet to and fro, to destroy any slight adhesion between the gold and the vellum: he also opens it at intervals, to see how the operation is proceeding. The beating is continued until each little inch-square piece of gold has become expanded nearly to the size of the vellum-leaves; and in order that the whole of the hundred and fifty pieces may be equally acted on, the packet is occasionally opened, and the inner pieces placed near the outside, to receive more action from the hammer.

When this degree of attenuation has been reached, the use of the vellum-leaves ceases, and that of the gold beaters' skin commences. The packet is opened, and each piece of gold, being taken out and placed on a kind of cushion, is cut into four pieces with a peculiar smooth-edged knife.

The pieces of gold, now increased in number from a hundred and fifty to six hundred, are interleaved with an equal number of pieces of the prepared gold-beaters' skin. The packet thus prepared is enclosed in parchment, and beaten in the same way as before, but with a smaller hammer. The pieces of gold become by degrees expanded, until they attain nearly the size of the skin-leaves. The packet is again opened, the leaves of gold are again cut into four each, and the quarters are again interleaved with gold beaters' skin. The cutting is, in this second instance, effected by the smooth edge of a strip of cane, since the thin gold would be liable to adhere to a steel knife. As the pieces of gold, now two thousand four hundred in number, would be too numerous to be beaten in one packet, they are divided into three parcels of eight hundred each, and each packet is interleaved with gold-beaters' skin, enveloped in parchment, and beaten in the same way as before. A third time these leaves expand nearly to the size of the skin-leaves; and by this expansion the necessary degree of thinness is attained. By the three beatings and the two quarterings, the gold is expanded to an area nearly two hundred times greater than it presented when in the form of a riband. The attenuation may be rendered more intelligible by stating that one hundred square feet of the leaf-gold weigh no more than an ounce—a result nearly as surprising as anything presented in the mechanical arts. Gold can be beaten to a much greater degree of thinness than that ordinarily used; but the waste occasioned by broken leaves, and the additional nicety and labour required, more than counterbalance the advantages.

When the last beating is finished, the packet is opened, and the thin leaves of gold removed one by one. The goldbeater makes use of a delicate pair of long pincers, made of white wood, and takes up the fragile leaves of gold one by one. Each leaf is laid down on a cushion, and blown out flat by the breath of the workman: if any of them have been broken or injured in the beating, they are thrown aside, to be remelted for future use; but otherwise each leaf has the ragged edges cut from it, so as to bring it to the size of about three inches and a third square. Small books are prepared, each containing twenty-six leaves of paper about four inches square; both surfaces of every leaf are rubbed with red chalk, to prevent the adhesion of the gold; and twenty-five leaves of gold are placed in each book. In this form the leaf-gold is sold, at fifteen to eighteen pence per book.

The French adopt the same general mode of proceeding as the English gold-beaters, but vary it slightly in detail. The laminated riband is cut into pieces an inch and a half long by an inch wide, and about 1-24th of an inch thick. Twenty-four of these are laid one on another on a smooth slab of steel, and hammered until they are two inches square. Fifty-six of those expanded leaves are made up into a packet, with two leaves of vellum between each. This packet is enclosed in a sheath, and is beaten with a hammer in the same way as in England. Indeed the hammering and quartering, and the use first of vellum and then of gold-beaters' skin, are the same in most of their features as those already described; but the French gold requires more hammering on account of the greater weight and size of the pieces at the commencement of the beating.

Two other metals, silver and copper, have sufficient ductility to be brought into the state of thin leaves by hammering; and both are used to a limited extent in this state in the arts. But these metals would fracture long before such a degree of thinness could be obtained as in the case of gold; and indeed the smaller value of the material renders it less important to economise material in this way: consequently leaf silver and copper are thicker than leaf-gold.

Two inventions of recent date may be briefly noticed here—Lane's ingot, and Bennett's gold-beating machine. In the usual method, described above, an ingot of *alloyed* gold is rolled and beaten; for there is always a little silver or copper mixed with the gold, to render it workable. Mr. Lane's suggestion is, to use a central plate of nearly pure gold, with two plates of alloyed gold on the two surfaces: the alloy to have any tint, or any degree of purity that may be desired. The three plates are heated nearly to fusion, which enables them to combine into one ingot, afterwards rolled and beaten in the usual way. The advantages of this method are assumed to be, that the colour of the leaf is variable at pleasure; and that the pure gold inside affords a highly malleable foundation, which carries the two surface-layers with it. The other novelty, Bennett's machine, is one among many contrivances which have been introduced to hammer the gold by machinery, instead of applying manual labour to it. Most of them have failed, on account of the nice adjustment of force necessary. In Bennett's machine a steam engine, by means of a band, gives motion to a fast-and-loose pulley, which in its turn causes the rotation of a shaft or axis. A cone on the axis, by means of a band, gives motion to another cone on another axis; the band, by minor adjustments is made to shift along the surfaces of the two cones, as a means of regulating the speed of the hammer connected with one of them. Smaller axes, pulleys, bands, wheels, crank-pins, connecting rods, guides, and cross-heads, allow the motion to be brought to bear upon the hammer, which thereupon rises and falls rapidly. The mould, or interleaved group of gold and vellum, or gold and gold-beaters' skin, is placed on an anvil, and is made to shift slowly as a means of equalising the action, after every blow of the hammer. Each upward movement of the hammer sets in motion a system of screws, nuts, axes, pulleys, and tooth-wheels, which cause the mould to shift its position slightly. Notwithstanding the ingenuity displayed in this machine, however, nearly all the leaf-gold manufactured is still beaten by hand.

GOLD-LACE MANUFACTURE. The beautiful substances, gold and silver lace, are produced by the application of a very thin coating of the precious metal to threads of silk. In the original and long-practised method, a stiffened thread is thus produced, applicable to the production of cloth-of-gold and other heavy tissues; but recently-invented processes enable manufacturers to apply gold to perfectly flexible thread. These two varieties may consequently be distinguished as *fibre-plating* and *fibre-gilding*.

Fibre-plating.—This is the process for the well-known gold and silver-lace, largely manufactured both by orientals and by Europeans. The Hindoo gold-lace is thus made. A rod of silver is roughed, and is plated with a leaf or film of gold; the thickness of the gold being to that of the silver in the ratio of 1 to 22. A little moisture and a slight pressure are all that are necessary to hold the gold in its place. The rod is made red-hot in a pan of charcoal; then taken out, hammered, and rubbed with a piece of wood. The rod, about three-quarters of an inch thick and six or eight inches long, is next drawn into wire, by a very rude apparatus, but one which the patient and ingenious Hindoo manages cleverly; it passes successively through many holes in a steel plate, each finer than the one that preceded it. The metal is heated and annealed after each drawing; and this series of drawings and annealings is repeated until the rod is brought down to the thickness of whipcord. Another set of wire-drawers, with greater skill and more delicate fingers, are next employed; they draw the metal through fifteen or twenty holes in succession, until it is reduced to the thickness of the finest hair. The gilt-silver is now too thin to be woven by itself; it would not possess sufficient strength; but it will serve as a covering for silk thread. The fine wire is flattened by a highly-polished steel hammer, working against an equally polished steel anvil; one blow with the hammer suffices to flatten eight or ten wires placed side by side; and the wires unwind from small bobbins or reels as the flattening proceeds. The orange-colour silk is then coated with the wire, by a twisting process, almost wholly without tools, and such as none but the delicate fingers of the Hindoo could perform.

English gold-lace is made in a manner which has recently been described by Mr. Bennoch, in a paper read before the Society of Arts, based on information obtained at the establishment of Messrs. Johnson and Simpson. Here, as in India, there is first the preparation of a rod of silver; then the coating of the silver with gold; then the reduction of the rod to the state of wire; and finally, the twisting of the wire round orange-coloured silk thread. The silver best suited for this purpose is obtained from lead, and is characterised by great tenacity and toughness. It is purchased in the form of a cake, which is melted to a white heat over a charcoal fire, and poured into an ingot mould made of iron or copper. The silver ingot so cast is about two feet long by two inches in diameter. It is brought to a red heat over a charcoal fire, and is beaten with hammers until its length is increased twenty per cent.; its substance being also rendered more dense and compact, by the fibres being then in parallel directions. Then begins the process of reduction. The ingot is drawn through a hole with a steam-engine force of 16-horse power, reducing its diameter and increasing its length. Again and again is this done, ten or twelve times, a smaller die being used each time. The attenuated rod is then thoroughly cleansed, and is ready for the application of the more precious metal. As the gold is applied in the form of leaf, and as all the leaves are of about equal thickness, different qualities of gold-lace are produced by varying the number of gold leaves laid on one over another; the commonest kind, for livery-lace, for the ends of muslins, and for skein-thread exported to India and China, have about ten layers of gold leaf; the best kind, for military purposes and for bullion-embroidery, have thirty; and between these extremes there are many intermediate kinds. The leaves are piled one on another to the requisite number, and such piles are laid side by side till they equal the length of the silver rod; the rod is rolled gently upon them, and the gold slightly adheres, without the intervention of size, water, or any other agent. The rod so overspread is enveloped in paper, tied round with a peculiar kind of cord, and placed in the centre of a heap of lighted charcoal; the paper and cord do not consume until the bar becomes nearly red-hot. The rod, while hot, is burnished with a blood-stone, to expel any air that may remain between the gold and silver, and to increase the closeness of contact of the two metals. When cool, the rod is coated with wax, and is ready for the wire-drawing process. The drawings, heatings, and annealings, are very numerous; for it is necessary to carry on the process of attenuation by minute degrees. So long as steel dies, or perforations in steel plates, were alone used, the silver-gilt rod could not be brought finer than 1000 yards to an ounce of metal; but now, perforated rubies are used for the finer kinds, and an ounce of the metal can be brought to the surprising length of a mile and a quarter. Concerning this invention, Mr. Bennoch said:—"There are not more than three men in London capable of perforating and setting these ruby dies properly; and one man, who works probably not more than three hours a day on the average, has received from one wire-drawing firm as much as 500*l.* or 600*l.* in a single year." Even this wire, finer than any human hair, has so much tenacity, that a piece twelve inches long will bear twelve ounces weight. The wire, after being slightly deepened in tint by passing over a heated cylinder, is flattened in the flatting-mill. This consists of two small steel rollers exquisitely turned and polished; they are brought from Rhenish Prussia, and have had such a large amount of labour and skill bestowed upon them, that they command the enormous price of 120*l.* the pair. The wire, flattened to twice or thrice its original width, and proportionably reduced in thickness, is then twisted upon or around a silken thread, by the aid of bobbins, reels, and a spinning-frame. A beautiful gold thread is thus produced, applicable to the making of gold-lace, embroidery, fringe, &c. Perfectly golden as the exterior is, however, it is surprising how little real gold the thread contains; for, of the whole bulk, nine-tenths is silk, and only one-tenth metal; and, in the average kinds, one-fiftieth part of the metal only is gold, the rest being silver; so that the gold constitutes no more than one five-hundredth part of the substance of the thread. Estimated by one man's labour, it takes 700 hours to reduce the ingot of silver, weighing about 400 ounces, to the finest wire; so extremely numerous are the drawing processes; in the finest kind, the ingot would be elongated to 500 miles of wire. Only 8 ounces of gold are applied to the ingot of 400 ounces; consequently, as a mile and a quarter of the finest silver-gilt wire weighs only one ounce, one ounce of gold suffices to envelope more than 60 miles of such wire.

It has long been believed that the electro-metallurgic process will ultimately be rendered applicable, both to fibre-plating and fibre-gilding, either in the thread or in the fabric. Up to the present time, no such processes have actually succeeded as substitutes for gold-lace made on the mechanical system above described; but we shall presently have to notice one applicable to other purposes.

Silver-lace is made by plating silken thread with a flattened wire of silver. The processes are analogous in principle to those just described, but of course less elaborate and less costly.

Fibre-gilding.—The gilding of fibre has lately occupied a good deal of attention. Chemists and manufacturers have long sought for a mode of coating fibres quickly with gold by some chemical process, as a substitute for the slower and more costly mode of fibre-plating. The French government several years ago offered a prize to the inventor of any such process; but no one earned it by success. Electro-metallurgy then seemed to open a new path, and many ingenious researches were made; but it was found that, although gold could easily be made to attach itself to the thread, the thread was long in drying through being soaked with a solution, and dried without lustre; while the foundation was too soft to admit of burnishing. In short, the brilliancy of gold-lace was not at all imitated by this product.

After many chemical experiments, Mr. Albert Hock succeeded in devising a mechanical contrivance. It is requisite that the silk should be of superior quality, free from knotty nibs and rough places; that the gum should be boiled out of it; and that the silk be dyed to a light orange tint. The silk thread is wound on bobbins; and when about to be gilt, it is transferred to a brass roller, around which it is wound so carefully as to admit neither of interstices nor overlapping. In its passage it passes through a trough containing a glutinous but transparent liquid. Leaf-gold is then laid on the coil of gummed silk, in pieces between three and four inches square; the cylinder being made to rotate partially to aid this application. Leaf after leaf is applied, until all the silk is covered. The gold is then pressed down upon the silk by a piece of cloth or wash-leather fastened to a piece of wood. One side of the silk thread becomes thus gilt. To gild the entire thread, it is transferred to another cylinder: during the passage the gilt side necessarily winds next to the brass on the second cylinder, leaving the ungilt part of the thread exposed, to be treated in the same manner. If it is desired that the woven fabric should present a rich alternation of gold and colours, the silk thread can be dyed of any colour chosen, and only one side or half of it covered with gold. The finished thread is wound upon boards or planchettes, ready to be applied to weaving, lace-making, fringe-making, or any other purpose. The advantages of this gilt fibre over gold lace are—that the material is light and pleasant for garment fabrics; and that, owing to its lightness and perfect flexibility, it can be wound and woven with perfect facility. The disadvantage is, that it cannot be made to present the brilliant and dazzling effect of thread plated with gold. As regards cost, it is said that the finest plated thread, selling at 8*s.* per ounce, measures 550 yards to the ounce; and that gilt thread of equal fineness and length, but weighing only one-third of an ounce, sells at 5*s.* The gilt fibre is dearer than the plated when estimated by weight, but cheaper when estimated by length. Although good gold is necessary for the best work, any combination of gold and silver, gold and copper, silver and copper, or all three, would suffice, if applied in the form of leaf. In some varieties of gauze scarfs the leaf metal used is wholly copper.

Mr. Hock's method of fibre-gilding is not the only one practised. Mr. Green obtained a patent in 1853 for a mode of covering thread with gold, ultramarine, emerald green, and various kinds of coloured powders. He employs metallic powders in the following way:—The thread is first dyed in the usual way; then wound upon a reel; then passed rapidly over a gas-flame to singe off loose filaments; then passed over a roller which dips into a trough of transparent gum; and then between pads of leather to remove any superfluous gum. Thus far prepared, the thread passes over a roller which dips into a trough containing gold powder or any metallic colour in a pulverulent state; by which means it becomes coated with a very thin metallic layer. After this the layer is dried. In one variety of the process the gumming compound is mixed with the metallic powder, instead of being applied previously to the thread. A slight degree of polish is given to the gilt thread by passing it between highly-polished steel rollers.

Other inventors have been at work in the same direction. The Prussian Industrial Association offered, for many years consecutively, a prize of 1000 thalers and a gold medal to any one who should invent an effective mode of gilding silk, on condition that the silk underwent no alteration in other respects. After many unsuccessful competitive attempts, Dr. Kroning of Stolberg gained the prize. The method he invented is applicable either to woven or unwoven silk. The exterior metallic surface is brilliant, and yet the thread remains perfectly flexible. When soiled, the thread or fabric may be washed in soap and water, and pressed lightly before drying.

Electro-gilding, we have said, has not yet been rendered applicable in the gold-lace manufacture. There is one invention, however, by M. Burot, which relates to the gilding of woven stuffs. The textile material to be gilt, whether made of silk or any other fibre, is dipped into a solution of nitrate of silver and ammonia. After remaining in this solution about two hours, it is taken out, and, when dry, exposed to a current of pure hydrogen gas, which reduces the salt, and leaves the silver in a metallic state on the stuff. A silvered surface is thus obtained, which can easily be coated with gold by the electro-metallic process. Gilt and silvered fabrics of considerable beauty are thus produced.

GOLD-LEAF ELECTROSCOPE. [Electricity, Common; Electrometer.]

GOLDEN FLEECE. [Argonauts.]

GOLDEN NUMBER, so called from its having been formerly written in gold letters in the almanacs, is the year of the cycle of nineteen years in which the current year falls. To find it, add one to the year of the Christian era, and divide by nineteen, the remainder is the golden number of the year; but if there be no remainder, then nineteen is the golden number. For the derivation and use of this number, see Periods of Revolution; Metonic Cycle.

GOLDEN RULE, a name given to the rule of three, from its universal use. [Proportion.]

GOMER CHAMBER. [Chamber.]

GO'NDOLA is the name given to the pleasure-boats at Venice, which are very numerous, and serve as a substitute for the coaches and carriages of other cities. The town being built on many little islands, divided by numerous canals, people of every condition are obliged to make frequent use of the gondola, in order to proceed from one district to another. The gondola is shallow, long, and narrow, pointed both at the head and stern, and rowed by either one or two men. It is generally from 25 to 30 feet in length, and 5 feet in width in the middle, where a square cabin is constructed for the use of the passengers. The cabin is furnished with commodious seats, and has glazed windows and black curtains. By a law of the ancient republic, these cabins were uniformly covered with black cloth and hangings, and the gondolas themselves painted black; no distinction of ornaments being allowed, except with regard to the gondolas of foreign ambassadors on the occasion of public ceremonies. The gondolieri, or boatmen, formed an important body or corporation, amounting to several thousands: they were famed for their wit, often licentious, as well as for their skill and honesty. Since the fall of the republic the number of gondolas has greatly diminished, owing to the decrease of the population and its reduced fortunes. Byron, in his 'Beppo,' st. 19 and 20, describes the singularly dark appearance of the gondola,—"just like a coffin clapp'd in a canoe."

GONFALO'NE, GUNTFANO'N, a word of Teutonic origin, derived from *gund*, which in the Frankish and Vandalic dialects meant "war," or "fight," and *fano* or *fahne*, which in German means a "flag" or "standard;" the two together mean a "flag of war." (Wachter, 'Glossarium Germanicum,' art. "Gund;" and Ducange, art. "Guntfano.") Both the French and Italians of the middle ages adopted the word, and the latter corrupted it into "gonfalone," and called the officer whose duty it was to carry the ensign "gonfaloniere." We read of the gonfaloniere of the Holy Church, who was the commander-in-chief of the papal forces. The title of Gonfaloniere di Giustizia was given to a high magistrate of the republic of Florence, appointed by the constitution of 1292. [Dante, in Biog. Div.] The republics of Siena and Lucca had also magistrates called gonfalonieri.

GONG, a Chinese musical instrument of percussion, made of a mixed metal of copper and tin, in form much like the cover of a large culinary caldron, being circular, varying from about 15 to 20 inches in diameter, and having a rim of from 2 to 3 inches in depth. It is struck by a kind of drum-stick, the head of which is of hard leather. The sound or sounds of this instrument—for it produces many jarring ones simultaneously—can hardly be called musical; and in fact the gong, which is very powerful, is only used for the purpose of making sonorous signals, of marking time, and of adding to the clangor of the martial instruments used in war.

GONIO'METER (from two Greek words γωνία, an angle, μέτρον, a measure) is the name of an instrument employed to determine the angles at which the planes of crystals are inclined to each other. [Angle; Plane.] The principle of the common goniometer is simply this. It may easily be shown that if two right lines intersect one another, the opposite angles thus formed will be equal. Hence, regarding the point of intersection as a centre, about which either of those right lines is free to revolve while the other remains fixed, if we suppose one of the edges of a solid bounded by plane surfaces to be applied to that centre, so that the edge may be perpendicular to the plane in which the two right lines are situated, and then suppose the lines to coincide with the two contiguous planes of the solid, it will be evident that the divergence of the lines will be the measure of the inclination of the planes. A graduated arc being now adjusted to the line which we supposed fixed, the position of the other line would indicate the number of degrees at which the planes of the solid were inclined to each other. As this instrument, however, when applied to laminated substances, such as crystals, is incapable of affording results sufficiently accurate to determine the species to which the crystal belongs, in consequence of the frequent irregularity of the fracture and the ordinary minuteness of the planes, we shall, without dwelling longer upon its construction, proceed to describe the more perfect instrument invented by Dr. Wollaston, and called the *reflective goniometer.*

It is well known that a ray of light falling upon a polished plane is reflected at an angle equal to the angle of incidence, and that to an eye situated in the direction of the reflected ray the object from which the ray emanated will appear as much below that plane as it is really above it. If therefore we place one of the planes of a crystal in such a position that the reflection of an object above the plane may appear to coincide with another object beneath, and then turn the crystal until the reflection of the same object above (from the second plane of the crystal) shall again appear to coincide with the same object below, it will readily appear that the arc which the crystal will have described will be the measure of the supplement of the inclination of its two planes, that is, the difference between that inclination and 180°. In turning the crystal the direction of the edge common to its two planes should not be altered, and the rays in both instances should be reflected from that portion of the planes nearest to their common edge, otherwise the observation will be affected by parallax. Such is the principle of Dr. Wollaston's reflective goniometer, by means of which the inclinations of planes whose area is less than the 100,000th part of a square inch may be determined within a minute of a degree, and which is equally effective whether the fracture be even or irregular. The instrument itself consists of a graduated circle mounted upon a horizontal axis, to one extremity of which is attached a moveable pin, having a slit for the purpose of receiving a small brass plate. To this plate the crystal is attached by means of a piece of wax, so that it may project beyond the edge of the plate. The pin (which is provided with a vertical and horizontal movement) is then raised or lowered until the reflection of any convenient object above appears to coincide with some other object beneath. The instrument being thus adjusted, the graduated circle is turned until a similar reflection is obtained from the contiguous side of the crystal. The arc which the circle will then have described will (as was before stated) be equal to the supplement of the inclination of the crystalline planes; but the margin of the circle being graduated in an inverted order, the true inclination is given without further computation, and may be read off by means of the vernier [VERNIER] with considerable accuracy.

GONIOMETRY, the measurement of angles; a name which might be substituted for TRIGONOMETRY, if it were advisable to alter established designations. The latter science, beginning with the measurement of triangles, made all that was known of the analysis of angular magnitude its own peculiar instrument. The various accessions which real goniometry received were therefore considered as additions to trigonometry: so that at this day, under a word which imports measurement of triangles, we have a science which wanders as far from the etymology of its name as geometry does.

GOOD FRIDAY, the name given to the day of our Saviour's Crucifixion. From the earliest ages of Christianity this day, emphatically called Good Friday, has been held as a solemn fast; its appellation of *Good* being applied to express the blessed effects which sprang from that important event.

It is in England only that this day has the appellation of Good: its ancient and appropriate title was Holy Friday, the Friday in Holy Week. Offices called *Tenebræ*, that is, "darkness," are sung on this day, and on its eve and morrow, by those belonging to the Romish faith. The lights are extinguished in reference to the supernatural darkness at our Saviour's Crucifixion, and nearly at the end of the service a solemn silence is observed throughout the church, which is suddenly succeeded by a tremendous noise, in token of the rending of the veil of the Temple, and of the disorder in which the very frame of nature was involved at that momentous event. Good Friday and Christmas Day are the only two days observed in England by a total suspension of business.

Cakes made for the day, called, from the mark impressed upon them, cross-buns, still, even in the metropolis, form the general breakfast on Good Friday; but are not further noticed. In some of the distant counties, such as are not eaten are preserved, to be used as an infallible cure for the faithful throughout the year. The practice of making cross-buns is supposed to have originated simply in the desire of marking on the only food anciently allowed on this solemn fast a symbol of the Crucifixion; but the custom of having some sort of consecrated bread is of great antiquity. The Jews and the Greeks had cakes, Jeremiah (xliv. 19) has "did we make her cakes to worship her;" and the Greeks gave the name of Boun (βουν) to their sacred bread.

Hospinian ('De Orig. Festorum,' fol. 61 b.) tells us that the kings of England had a custom of hallowing rings with much ceremony on Good Friday, the wearers of which would not be afflicted with the falling-sickness.

A sermon used to be preached on the afternoon of this day at Paul's Cross, at which the lord-mayor and aldermen attended in their robes.

Creeping to the Cross on Good Friday was another of the Popish ceremonies formerly practised in England. The ceremonial of it is given by Bishop Percy in the notes to the 'Northumberland Household Book.'

GOOSEBERRY. The *Ribes Grossularia*, indigenous to Britain and some other European regions of cool temperature, and also to the mountains of North America, at an elevation of from 2000 to 3000 feet above the level of the sea, is the origin of the many hundreds of kinds of this wholesome fruit now in cultivation. Its botanical position is described under RIBES, in NAT. HIST. DIV. Its use, as is well known, is more or less within the reach of every one. It is the earliest fruit for culinary preparations; and it may be preserved green for winter use, as also in a ripe state. The plant bears so abundantly that a large quantity may be thinned off for tarts, pies, sauces, &c., in the early part of the season, and still, if done judiciously, a sufficiency left for ripening. The gooseberry will ripen in the extreme northern parts of Britain, near the level of the sea; and in lat. 57°, even at an elevation of 900 feet, it acquires great perfection with regard to flavour. In hot seasons, in the southern counties, the fruit cannot endure full exposure to the direct rays of the sun, which sometimes make it appear as if scalded; under such circumstances evaporation takes place from the whole surface faster than the subjacent tissue can repair the loss: the consequence of which is a complete emptying of the superficial cells of the fruit, which produces death.

The temperature and other circumstances which various species of fruit require in the course of ripening are very important to be known, as they vary in all probability in every different species. In some cases the secretions are formed rapidly; growth is moreover quick from the period of flowering; and a rapidly-increasing temperature, attended by atmospheric moisture, is best suited to the perfection of the fruit: such is the case with the apricot. The fig, on the contrary, demands a long, steady, high temperature, and a dry atmosphere.

In the case of the gooseberry, it appears that the flavour is best where the low temperature of the north brings the fruit more gradually to maturity than it does in the south, where the fruit is in danger of being scorched, and where it ripens far too quickly to acquire the peculiar flavour which it attains in its favourite climate; and a different method of pruning and training ought to be practised accordingly. Thus in the north the branches should be left thin, so as to expose the fruit, and with the same view the spurs should be short. In the south the trees should not be laid so open, and the lateral young shoots, instead of being cut close in, immediately above the fruit-bud at their base, should have two buds left to produce leaves for shading the fruit in summer.

In the manufacturing districts of Lancashire and the adjoining counties the cultivation of the gooseberry has been brought to surprising perfection, at least as regards the size of the fruit: and this chiefly by the manufacturing classes, in consequence of prizes being awarded to successful competitors at the gooseberry-show meetings. Judging from the quality of the varieties grown for competition in this way, it appears that weight is the only qualification required; it is, however, much to be regretted that flavour is not also taken into account. From the neglect of this requisite, many of the fine Lancashire gooseberries are not at all worth cultivation, except on account of their coming to a size sufficiently large for cooking earlier than the smaller. For this purpose those with smooth skins should be avoided, because the skins become tough in the process of cooking.

For flavour, the small, or "Old English" kinds, are far the best, and indeed are the only sorts worth growing; but they do not look well among a dessert. We give below a list of such sorts as are proper for a selection, when flavour is the principal object; and another in which mention is made of the best Lancashire varieties, where flavour and size are in a tolerable degree combined.

Gooseberries are arranged systematically according as their *colours* are *red*, *yellow*, *green*, or *white*; and subdivided with regard to their *surface* being *hispid*, *downy*, or *smooth*.

Small, or Old English, Gooseberries.

Division 1. *Fruit Red:*
* *Surface hispid.*
1. Rough Red.
2. Small Red Globe.
3. Small Dark Rough Red.
4. Scotch Best Jam.
5. Red Champagne.
6. Keen's Seedling.
7. Raspberry.
8. Red Warrington.
9. Rob Roy.
* * * *Surface smooth.*
10. Red Turkey.

Division 2. *Fruit Yellow.*
* *Surface hispid.*
11. Early Sulphur.
12. Yellow Champagne.
13. Hebburn Yellow Aston.
* * *Surface downy.*
14. Rumbullion.
* * * *Surface smooth.*
15. Amber.
16. Yellow Ball.

Division 3. *Fruit Green.*
* *Surface hispid.*
17. Early Green Hairy.
18. Glenton Green.
19. Hebburn Green Prolific.
* * * *Surface smooth.*
20. Pitmaston Green Gage.
21. Green Walnut.

Division 4. *Fruit White.*
* *Surface hispid.*
22 White Crystal.
23. White Champagne.
24. Taylor's Bright Venus.
* * *Surface downy.*
25. Early White.
* * * *Surface smooth.*
26. White Damson.
27. White Honey.
28. Crystal.

Of the above, Nos. 1, 3, 4, 5, 7, are excellent for preserving. No. 14 is the best sort for bottling green. The earliest are Nos, 9, 11, 17, 21, 25, 27; and the latest is No. 8.

Large, or Lancashire, Gooseberries.

Division 1. *Fruit Red.*
* *Surface hispid.*
Leigh's Rifleman.
Lomas's Victory.
Melling's Crown Bob.
Boardman's British Crown.
Bratherton's Huntsman.
* * *Surface downy.*
Berry's Farmer's Glory.
* * * *Surface smooth.*

Farrow's Roaring Lion.
Rider's Scented Lemon.

Division 2. *Fruit Yellow.*
* * * *Surface smooth.*
Dixon's Golden Yellow.

Division 3. *Fruit Green.*
* *Surface hispid.*
Princess Royal.
Hopley's Lord Crewe.
* * *Surface downy.*
Parkinson's Laurel.
Collier's Jolly Angler.
* * * *Surface smooth.*
Massey's Heart of Oak.
Edwards's Jolly Tar.
Large Smooth Green.

Division 4. *Fruit White.*
* *Surface hispid.*
Cleworth's White Lion.
* * *Surface downy.*
Woodward's Whitesmith.
Wellington's Glory.
Saunders's Cheshire Lass.
* * * *Surface smooth.*
Cook's White Eagle.

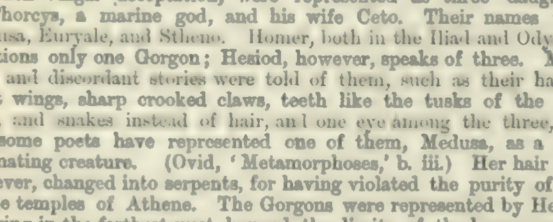
The Pruning of Gooseberries is performed any time during the winter, and before the sap begins to be in motion in the spring. The operation consists in removing all cross laterals, so as to leave the branches as nearly as possible at regular distances, round an open centre, except where the heat of the climate renders it necessary to retain branches in the centre for shade; and the points of these branches, where too extended, or weak, should also be shortened to some well situated bud. Very strong shoots, assuming the character of robbers, should be cut clean out, except such as may be occasionally wanted to supply vacancies. It is however better economy, with regard to the health of the tree, to pinch off the tops of these strong shoots in the summer, and thus prevent their monopolising the sap from the other parts. Suckers, on the same principle, should be prevented from growing at the root.

The branches in all cases should be pruned to a single terminal shoot. In short, the plant should exhibit a regular appearance without any overcrowding in one part and deficiency in another.

GORGE, in fortification, is the name given to that part of any work which lies directly between the interior extremities of its faces or flanks, as between *f* and *g*, *fig.* 1, BASTION.

The prolongations of the magistral lines of two collateral ramparts or walls, till they meet in the interior of any work, as *f* B, *g* B, are called the demi-gorges of that work.

GORGONS, GORGONES, are certain mythological personages, who, in their vulgar acceptation, were represented as three daughters of Phorcys, a marine god, and his wife Ceto. Their names were Medusa, Euryale, and Stheno. Homer, both in the Iliad and Odyssey, mentions only one Gorgon; Hesiod, however, speaks of three. Many wild and discordant stories were told of them, such as their having great wings, sharp crooked claws, teeth like the tusks of the wild boar, and snakes instead of hair, and one eye among the three, and yet some poets have represented one of them, Medusa, as a very fascinating creature. (Ovid, 'Metamorphoses,' b. iii.) Her hair was, however, changed into serpents, for having violated the purity of one of the temples of Athene. The Gorgons were represented by Hesiod as living in the farthest west, beyond the limits of the known world, by Night and the Hesperides; later writers placed them in the unknown regions of Libya. They were said to have had the power of turning into stone all those who gazed at them. At last Perseus, the son of Jupiter and of Danaë, set out, encouraged and assisted by Athene, to encounter the Gorgons, and he conquered them, cut off the head of Medusa, from whose blood, dropping on the ground, the horse Pegasus was engendered. He then gave the head of Medusa to Athene, who fixed it on her ægis or shield, which ever after had the power of turning the beholders into stone. In representations of Athene the head of Medusa frequently occurs. In Greek sculpture of the best period the features of Medusa are extremely beautiful, but with a certain stern and terrible expression, latent however rather than fully evolved. At times, in sculpture, and on coins and gems, the head is almost hideous. A Gorgon's head was the usual ornament on the upper part of the breastplate of a Roman emperor: one is figured on the statue of Hadrian, in the Roman Saloon, British Museum. We give a cut of a Gorgon's head from a terra-cotta frieze in the British Museum, Græco-Roman Basement Room.



Gorgon's head, from a Terra-Cotta in the British Museum.

GOSPEL, derived from two Saxon words of the same meaning as the Greek *evangélion* (εὐαγγέλιον), which signifies "good news," is employed both by the authors of the New Testament and by modern theologians to denote the whole Christian system of religion, and also more particularly the good news of the coming of the Messiah. The books containing an account of the life of Christ were also called gospels by the ecclesiastical writers. Many such gospels were in circulation in the first three centuries, but four only, namely, Matthew, Mark, Luke, and John, were received by the fathers as of divine authority. Several of the other gospels are quoted by the fathers, but not as possessing authority to bind the faith of Christians; and Origen, who appeals to them more than any other writer, expressly says that the church received only four gospels. ('Hom. in Luc.,' i. 1.) We find no quotations from them in the writings of the apostolical fathers, with the exception of a doubtful passage in Irenæus (Lardner's 'Works,' vol. ii. p. 91): none of them appear to have been written till the 2nd century, and several not till the 3rd. The apocryphal gospels which had the widest circulation were, the Gospels according to the Twelve Apostles, the Hebrews or Nazarenes, and the Egyptians. The Gospel according to the Hebrews, which is supposed by some critics to be the same as that according to the Twelve Apostles, was written, in all probability, in the beginning of the 2nd century, in the Syriac language. It appears to have been taken principally from St. Matthew's Gospel, with additions from the other evangelists, and oral tradition. It has been maintained by some critics that this gospel was written by St. Matthew, and that the Greek gospel bearing his name in the New Testament was only a translation of it.

The Apocryphal Gospels which are extant are, 'The Gospel of the Infancy of Christ,' alleged to have been written by Thomas, and by Matthew: it was received as genuine, and is found in the works of St. Jerome, who lived in the 4th century; the 'Gospel of the Birth of Mary;' the 'Protevangelion of James,' and the 'Gospel of Nicodemus.' These were published by Fabricius, in his 'Codex Apocryphus Novi Testamenti,' 2 vols. 8vo., Hamb. 1719-1743, and by Jones, with an English translation, in his 'Method of Settling the Canonical Authority of the New Testament,' 3 vols. 8vo. Lond. 1736-7. The 'Gospel of the Birth of Mary,' the 'Protevangelion,' and the 'Infancy of Christ,' were held in reverence by, and contained some of the principles of, the sect of Gnostics. These gospels appear to have been written with the object of supplying the supposed deficiencies of the canonical gospels. They abound in absurd and improbable tales, principally relating to the early life of Christ, and contain hardly any particulars concerning his public life and ministry. The writings of the fathers give the names of many other gospels, of which the following is an alphabetical list:—Andrew, Apelles, Barnabas, Bartholomew, Basilides, Cerinthus, Ebionites, Encratices, Eve, Jude, Judas Iscariot, Matthias, Marcion, Merinthus, Peter, Philip, Seythianus, Tatian, Thaddæus, Thomas, Valentian. (Jones 'On the Canon,' vol. i., p. 145-150.)

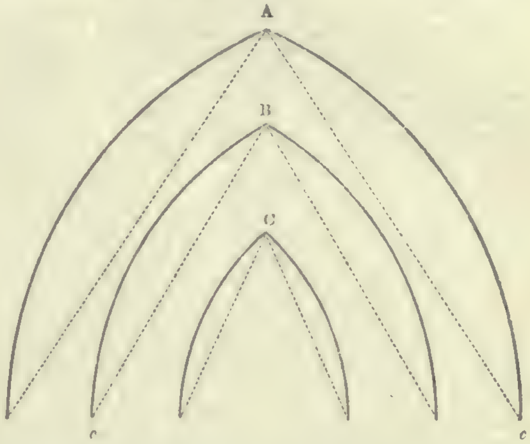
From the many verbal agreements and striking differences in the gospels of Matthew, Mark, and Luke, it has been maintained by many critics that they were derived from an original gospel common to them all, which is supposed to have been drawn up by the disciples who attended the person of Christ; and that this document, which was afterwards lost, is quoted by Clement and Origen under the title of 'The Gospel According to the Twelve Apostles.' This hypothesis was first introduced into this country by Dr. Marsh, in his dissertation 'On the Origin of the first three Gospels,' and has been maintained in Germany by Michaelis, Semler, Lessing, Eichhorn, Gratz, Kuinoel, Bertholdt, and other celebrated critics. An interesting account of this controversy is given in the preface to the English translation of Schleiermacher's 'Critical Essay on the Gospel of St. Luke,' Lond. 1825, 8vo.

GOTHIC ARCHITECTURE. The term Gothic has long been almost universally assigned to that form of architecture which prevailed through a large part of Europe during the middle ages. First applied as a term of reproach, as synonymous in fact with barbarous, and having in itself no special appropriateness, since it was certainly not by the Gothic races, properly so called, that the style was introduced or practised, it is not surprising that writers on Gothic architecture have usually deemed it necessary to enter a more or less formal protest against its use. So generally is the term employed, however, so much has it indeed become incorporated into our language and literature, that it would be hopeless to attempt to replace it by a more fitting one, if even a more fitting one presented itself. But hitherto, at least, no satisfactory substitute has been suggested. The term Christian Architecture at present much in vogue, is palpably a misnomer. What we must continue to call Gothic architecture, was never intended by its originators as in any way antagonistic to what it is now the practice to term Pagan Architecture; nor is there anything essentially Christian in the Gothic style, though it has been chiefly employed on ecclesiastical structures. As Mr. Petit pertinently remarks, had St. Paul succeeded in converting the Athenians, no one can suppose that they would have constructed their churches in this style. In the modern Greek church it has never been employed. Among Protestants it was almost equally unused before the Gothic revival which dates little more than a quarter of a century back: the fall of the true Mediæval Gothic has indeed been by its more ardent admirers attributed to the growth of the Protestant spirit. It cannot be consistently styled Christian, if even Roman Catholicism be taken as the exclusive type of Christianity, for in Rome itself, the very heart and centre of Catholicism, it has notoriously never obtained a footing. The term Christian Architecture is indeed as inaccurate as it is affected and sectarian. Nor can the term Pointed Architecture be admitted as a desirable substitute for Gothic,—though (arched being understood) it is sufficiently significant of its ultimate development. But Gothic architecture is now generally felt to be unduly restricted when it is confined to that branch of it characterised by the pointed arch. Gothic architecture, in fact, comprehends two great branches—Round-Arched Gothic, known as Romanesque, and Pointed-Arched, or that to which the term Gothic is popularly restricted.

The old vexed question of the origin of Gothic architecture, and of the pointed arch, its assumed characteristic, loses much of its significance under the view of its history now gaining general acceptance. Gothic architecture it is seen in reality traces back its pedigree to the architecture of the ancient Romans. As the empire became consolidated, a style of architecture differing more and more from that of Greece was developed. Its distinctive feature was that of the semi-circular arch, as that of Greece was the horizontal beam. Until the utter ruin of Roman nationality and civilisation, the arcuated as opposed to the trabeated mode of construction continued to be practised. When the nations which had formed a part of the Western Empire began to emerge from the gloom which overshadowed them after its fall, the churches they erected were imitations, however poor and feeble, of the basilicas of ancient Rome. Gradually those features of the buildings, whether constructive or ornamental, which go to make up what in the aggregate is called a style, diverged farther and farther from the ancient models, and there was evolved what, from its evidently derived, though ultimately independent character, has been designated the Romanesque. In Italy, and the south of Europe generally, this style continued to retain more resemblance to the original, whilst north and west, where in fact the Germanic races prevailed, it underwent extensive and comparatively rapid changes. Hence some writers would retain the name Romanesque for the architecture of the nations of Roman parentage, assigning that of Round-arched Gothic to the early architecture of the German races. But this ethnological distinction scarcely holds with sufficient tenacity to make it the basis of a separate classification. The simpler and better course seems to be, to regard all the round-arched styles of Mediæval date, as Romanesque; the so-called Lombardic, Norman, &c., being merely national varieties of a normal type. That form, which the divergence from the Roman type assumed in the Eastern Empire, is a wholly distinct thing, and, for the reasons assigned under BYZANTINE ARCHITECTURE, fully entitled to be regarded as a separate and independent style.

Thus, then, we take as the starting point in the history of Gothic architecture the formation of the Romanesque style; but to speak of its full development, its distinctive features, and æsthetic character, and to notice ever so cursorily the phases it assumed in different countries, would swell this article to a very inconvenient length. We shall defer, therefore, a general notice of the round-arched branch of Gothic architecture to the article ROMANESQUE ARCHITECTURE, and a more particular notice of that section of it which we are familiar with in cathedrals and churches of our own country to the heading NORMAN ARCHITECTURE; and here confine our attention to Pointed Gothic Architecture, and especially to English Pointed Gothic.

The question of the origin of pointed architecture, as springing from the invention of the pointed arch, or arch of two centres, was formerly eagerly debated by writers on Gothic architecture. That such discussions were based on an erroneous assumption, we have seen in the article ARCH. The pointed arch was known and used long before its adoption by the Gothic architects. Its employment was forced on them by constructive requirements, either in order to overcome the difficulties arising out of the necessity of vaulting over large and variously formed spaces, as Ware, Whewell, and other able writers think, or, according to the views of Mr. Scott, in order to get rid of the powerful outward thrust of a round arch of large span, or heavily loaded. Be, however, the original inducement to its use what it may, its introduction was the commencement of an entire change in the character of Gothic architecture wherever that style was practised. The pointed arch and arched vaulting became, in fact, the prime principle of Gothic construction. Here, therefore, it may not be improper to explain the different kinds of pointed arch, which are such that the style named from it contains in that respect, owing to its being struck from two centres, a source of variety unknown to any other; for the single centred, or round-headed one, can be varied only by making it more or less than an exact semicircle, in which former case it approaches the horse-shoe curve, and in the latter becomes a segmental or scheme-arch. But arches struck from two centres, and therefore pointed by the two curves meeting each other, may be of various degrees of acuteness, and exhibit great difference as to the proportion which the chord or span of the arch bears to a vertical line drawn from it to the vertex or crown. In the semicircular or one-centred arch the span is invariably equal to double the radius, or line drawn from the centre to the intrados, or curve bounding the aperture; but in the narrow acute lancet-arch, which is extra-centred (that is, is struck from centres on the outside of the arch), the span is less than the radius, and the arch itself consequently narrow and tall, and more or less so in proportion as the distance between the centres is increased or diminished. In the equilateral arch, sometimes distinguished as that characteristic of pure Gothic, the centres coincide with the extremities of the span, which is equal to the radius, so that the chord and the two lines drawn from the centres to the vertex form an equilateral triangle. This species of arch is called by the Italians the *sesto acuto*, because the lines just mentioned are equal to the radius, or one side of a hexagon described within a circle struck by it. When the radius is less than the span,—or, in other words, the centres are on the span itself,—the arch becomes an obtuse-pointed one; and it is hardly necessary to observe, that the arch becomes more obtuse in proportion as the centres are brought nearer each other; for were they to unite, the arch would become a single-centred and semicircular one. All these varieties may occur in the same example; because, if the mouldings be very numerous, and occupy a great space, as is frequently the case in doorways, being all concentric, some of the curves will describe inner-centred or obtuse, others extra-centred or acute arches, as may be perceived by this diagram, which, omitting the intermediate mouldings, will serve to exemplify the several varieties of the two-centred arch above defined.

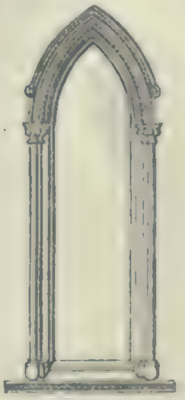


The centres in the intermediate figure (B) being at *c c* respectively, and the line joining *c c* being also the chord or span, B is an equilateral arch: A and C are respectively obtuse and acute arches, the centres in the arch A being on the span, and in C being without it, as above explained. The four-centred arch, so prevalent in our later or Perpendicular Gothic as to be almost characteristic of it, is, on the contrary, struck from two centres on each side, one on the span of the arch, and the other below it, as will afterwards be explained.

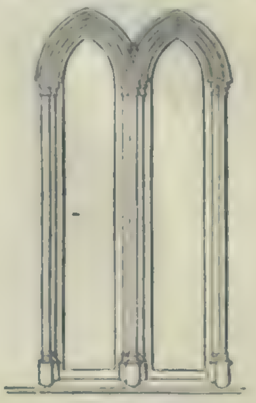
Pointed Gothic, as a distinct style, dates from near the close of the 12th century. Mr. Hope, in his 'History of Architecture,' with many of the older Continental as well as English writers on Gothic, considers the pointed style to have originated in Germany, but its birthplace is now more commonly admitted to be France. Some have indeed sought to identify its origin with Suger, the famous church-building abbot of St. Denis; but this is at least doubtful. All that can with safety be asserted is, that at this time France was the great centre of ecclesiastical architecture, and that from her proceeded those new principles which were eagerly adopted by the architects of other countries. But the application of the pointed arch was not a sudden thought. For a long time there had been a growing approximation towards those characteristics of which the pointed arch permitted the full expression. In the quadripartite vaulting of Romanesque crypts we see the first application of that system of vaulting which assumed its full importance in the pointed style; and pointed arches not infrequently occur along with semicircular ones in the later examples of Romanesque, of what has been called the Transition style. But, in fact, Gothic architecture was always in a transition state; and it should be borne in mind when any particular style or form of Gothic is spoken of, that the subdivision into styles, classes, or periods, is merely a matter of convenience. Gothic classification has been dwelt on with very needless emphasis in this country. It has been attempted to define, not only the broad divisions, but the minor subdivisions, and to separate each by a distinct date of origin and termination. Now nothing is more certain than that, during the whole period when Gothic architecture was practised, there was a continuous course of modification, change, or transition, and that in some places the change advanced much farther and more rapidly than at others. The true Gothic architects seem never to have cared much for precedent. Those who had advanced far in constructing a cathedral on the old round-arched type, at the introduction of the pointed arch, without hesitation availed themselves of it in completing their building. If a church of early pointed date had subsequently to be altered or enlarged, they made the new part in the style of their own day, not of that of the builders of the church. Hence we see everywhere a comparatively brief period during which a particular recognised style of Gothic was practised with only such variation as may be readily accounted for by the individuality of the designer, the necessities of the locality, and the like; but, then, on both sides of that middle period there is an admixture more or less marked of the characteristics of the style which is passing away, or of that which is as yet only thus foreshadowed. Thus, with the period before us, we may see in our own country pointed Gothic arches, and other traces of the coming style, very instructively intermingled with Norman round arches, &c., in parts of Canterbury Cathedral, the east end of Chichester and the choir of Lincoln cathedrals, parts of the fine abbey churches of St. Albans, Glastonbury, and Malmesbury, and in several other of our cathedrals and larger parish churches; and in France in Chartres Cathedral, the abbey of Fontenay, the churches of Pontigny, St. Germer, and many others, and notably in those of Central France. And in speaking of these French churches, it deserves to be noticed, that this transitional style, in which the characteristics of the Romanesque and the Pointed are so intimately blended, did, in fact, continue its existence through Central France, Lorraine, and elsewhere almost to the end of the 13th century,—in other words, during nearly the whole range of the early pointed style. (De Caumont, 'Bulletin Monumental,' and 'Architecture Réligieuse.')

The nomenclature and chronology of the styles of pointed Gothic generally accepted in this country, are those proposed by the late Mr. Rickman in his 'Attempt to Discriminate the Styles of Architecture in England.' Taking the Anglo-Saxon and Norman as pre-Gothic divisions, he reduced the classes of Gothic proper to three: *Early English*, which prevailed from the end of the reign of Henry II. to the end of that of Edward I., or from 1189 to 1307; *Decorated English*, from the beginning of the reign of Richard I. to the end of that of Edward III., or from 1307 to 1377: and *Perpendicular English*, from the beginning of the reign of Richard II. to the end of that of Henry VIII., or from 1377 to 1546. His arrangement was doubtless an improvement, because a simplification of those which preceded it; but though seemingly specific it is really deficient both in precision and accuracy. The terms Early English, Decorated, and Perpendicular, are formed on no common principle. If Early English were a good title, some other terms referring to time should have been combined for the later periods. Decorated is in itself apt enough for the second style by way of comparison with the style which preceded it, but most unapt as compared with its successor. So, again, Perpendicular seems sufficiently distinctive when the window tracery and panelling of the style are regarded, but it is characteristic of little beyond those features: the extension of the term to the end of the reign of Henry VIII. is generally given up. Later writers (as Mr. Sharpe) have proposed a geometrical arrangement:—*Lancet* (1190—1245), *Geometrical* (1245—1315), *Curvilinear* (1315—1360), *Rectilinear* (1360—1550); or (as Messrs. Garbett and Fergusson) a chronological one:—Plantagenet, Edwardian, Tudor; which have at least the merit of defining by sharply marked outlines. Another classification has however been proposed, which has the opposite merit of being less rigid in its boundaries, while it is not less explicit in expression. It is that of ***First Pointed, Second*** (or ***Middle***) ***Pointed***, and ***Third Pointed***; corresponding generally to the Early English, Decorated, and Perpendicular of Rickman. This, some of the more systematic of its partisans have again subdivided and formularised; but if it be taken as a mere convenient form of expression, it will, we believe, be found superior for all practical purposes to any other. Continental writers very generally speak of the Gothic of the 13th, 14th, or 15th century; and as it fortunately happens that the styles prevalent during those centuries are well marked varieties, this mode of speech is a very good one. But in France at least (and with French Gothic our own is nearly cognate as well as synchronous) the terms *Ogival Primitif*, *Ogival Secondaire*, and *Ogival Tertiaire*, are recognised definitions; and with them our own First, Second, and Third Pointed Gothic would exactly correspond, if we understood that those terms were merely convenient expressions for the Gothic of the 13th, 14th, and 15th centuries respectively. In fact, whatever classification be adopted, there seems a general inclination to make these centuries its chronological basis. Without therefore venturing to discard Rickman's terminology, we may now say that Early English, or First Pointed, may be taken to stand for the architecture of the 13th century; Decorated, or Second Pointed, for that of the 14th; and Perpendicular, or Third Pointed, for that of the 15th: it being clearly understood that neither style was really circumscribed within strict dates.

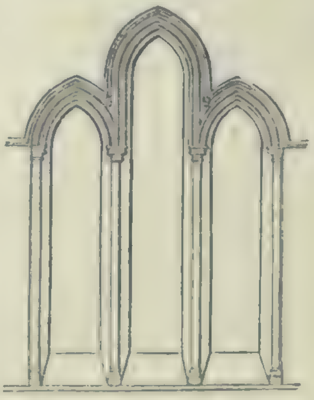
The Early English, or First Pointed style, had arrived at its full development in the early part of the 13th century. Characteristic contemporaneous examples in England and France are the cathedrals of Salisbury and Amiens, commenced respectively about the year 1219. In both of these the round arch and massive columns of the preceding style have quite disappeared. The buildings are lighter, loftier, more graceful in their proportions, more beautiful as a whole, more finished in the details, distinguished by vertical rather than horizontal lines, and exhibiting a great advance in constructive power. In them, as Mr. Fergusson points out, are shown what continued to be characteristic points of difference between English and French cathedrals: the English showing greater length in proportion to width, less altitude, square instead of apsidal terminations, and more restraint in the ornamental details. Turning to the broad distinctive forms and details of the style as shown in English buildings, we observe that at first the arch was exceedingly acute, and employed chiefly where small span was required, as in windows, which at first consisted of a single aperture, then of two, either distinct, with a narrow space or pier between them, or combined together by means of a central pillar. This led to similar grouping of three apertures, the centre one of which rose higher than the others, and also to the practice of enclosing them within a larger arch, the space between which and the lesser ones was filled up with a circular arch, whereby the whole acquired not only greater variety, but that architectural distinctness and completeness of form in which the earlier kind of double-window was deficient on account of its outline sinking instead of rising in the centre, and it looking merely like two arches belonging to an extensive range. These gradations in the compositions will be clearly understood from the subjoined figures, the first and third of which are specimens from York Cathedral, the second from Winchester, and the fourth from Westminster Abbey: the mode shown in the last evidently led the way to that of decorating the window-head, by dividing it into smaller and more varied compartments of ornamental panelling, which, whether perforated or not, is known by the general term of tracery, and constitutes a species of embellishment predominating in all the varieties of Pointed Gothic, and likewise in all the different national schools of it.



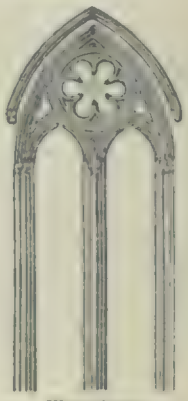
York.



Winchester.



York.



Westminster.

In the first class of our own First Pointed, or Early English, the openings of the windows are lancet-headed, and not only narrow but tall; that is, the part below the spring of the arch is very long in proportion to its width, a circumstance totally independent of the form of the arch itself, and therefore affording the greater scope for variety. In fact, we behold a striking difference in respect to proportions exemplified in the doorways of the same period; for although similar as to general character, and frequently, like the later double-window above represented, consisting of two arches divided by a central pillar, either single or clustered, with a circular compartment above them in the larger arch-head, the height from the ground to the springing of the arch is sometimes even much less than the width of the whole design, and not much more than double that of the smaller arches. The receding sides, or splays, of such doorways were as deep as those in the Norman style, and enriched with columns; and the dripstone, or hood moulding (for it is variously termed, and is the only moulding projecting from the wall, as all the others receded within its surface), not unfrequently rested upon carved heads. Instead of being placed upon pillars or cylindric piers, as in the Norman style, the pier-arches (so called in order to distinguish them from arches introduced in walls), which are mostly lancet ones, are placed upon piers with shafts attached to them, so as to give the whole a clustering form; but there is so much variety, both as to plan and the enrichment of capitals and other details, as to render it impossible to enter into particulars without numerous explanatory drawings from different examples. The buttresses have greater projection than the parts which appear to answer to them in Norman architecture. They are also narrower, and some of them are divided into two or more stages by set-offs, or horizontal splays, reducing the projection from the wall at every stage. Flying buttresses were now first introduced [BUTTRESS]. Gargoyles also first appeared at this period both in France and England [GARGOYLE], and were a part of the system now fully recognised of making even the inferior accessory features ornamental. The columns frequently consisted of a thick central pier surrounded by slender detached shafts; but clustered columns introduced during the transition period became general. Capitals were generally bell-shaped; with a round or octagonal abacus. The foliage on capitals and elsewhere was frequently a close imitation of local plants and flowers; and floral ornamentation became much more general. The mouldings are in the earlier examples often Norman or transitional in character, in the later Decorated; but those distinctive of the style are round or pointed, with very deep hollows and variously filleted. (See examples in Paley's 'Gothic Mouldings.') String-courses and labels were much more extensive and continuous than in the previous style. The mode of wall ornament called diapering was now first employed. The statuary and carving generally became much more artistic during the continuance of this style; and indeed nothing can in its way well exceed the richness and beauty of that of the east front of Ely, and the west front of Wells, cathedrals.

The use of groined vaults, pointed arched windows, and flying buttresses permitted the construction of walls of a less massive character than those of Norman date, and the carrying them up to a greater height. Spires were likewise built of a much greater altitude, and many of them are of an exceedingly elegant outline. Roofs were generally acute in pitch; and of open wood-work as well as stone vaulted. Parapets were generally plain. The characteristics of the painted glass of the windows of this and the two succeeding styles e indicated elsewhere. [GLASS PAINTING.]

Choir, Salisbury Cathedral.

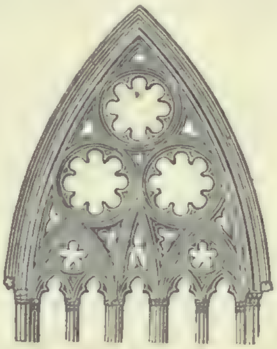
The most perfect English example of the First Pointed style is Salisbury Cathedral, which was begun by Bishop Poore about 1219, and finished about 1260—being therefore what is so rarely seen, a cathedral completed wholly in one style, and uniform in character throughout. Lincoln Cathedral, though not throughout First Pointed, is a noble example of the style. The nave and transept of Westminster Abbey afford another important example, the more noteworthy because possessing even more of the French than the English First Pointed character. Ely, Peterborough, Wells and Worcester, the east end of Winchester, the lady chapel Hereford, and York Minster, especially the unrivalled five-sister lancet windows. Ripon and Beverley minster, and the Temple church may be cited as among the important examples of the style; but the list might be greatly extended, especially by the addition of numerous parish churches.

In France, characteristic examples are the cathedrals of Sens, Amiens, Reims, Notre Dame de Paris, St. Dénis, Bayeux, Chartres (the nave); the abbey of Fontenay; the Ste. Chapelle at Paris; the churches of Pontigny, Trévière, Calvados, St. Germer, &c. Germany possesses a very interesting and beautiful specimen of the same style and period in the church of St. Elizabeth at Marburg, which is nearly contemporary with the cathedrals of Salisbury and Amiens, having been constructed between the years 1235 and 1283. It is fully described by Moller in his work on German-Gothic architecture, where it is illustrated by eighteen plates; and an elevation of its west front forms the frontispiece to the translation of Moller's text by Mr. W. H. Leeds. The cathedral of Magdeburg, another very fine example, shows more decidedly the influence of the French taste, an influence which strongly affected the course of German-Gothic. The choir of Cologne Cathedral (about 1270-1322) belongs to this style. Freyburg (1283-1330) is an example of the tendency of German-Gothic towards extravagance of ornamentation, with, in the open-work spire, &c., excessive lightness. The nave of Strasburg cathedral, Altenburg, and many other German churches, are of this period.

The transition from the First Pointed, or Early English, to the Second Pointed, or Decorated style, was made by almost imperceptible steps. The dividing line is variously drawn between 1270 and 1307: as for its termination, some one or other year somewhat anterior to 1379 is usually assigned: but as we have said, it is safer, and sufficiently precise, to regard the Second Pointed as the style of the 14th century, remembering that towards the close of that century some important buildings of unquestionably Third Pointed character were erected.

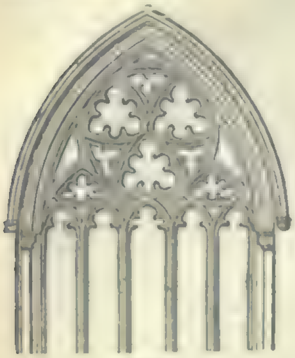
As compared with those of the First Pointed, the churches of this period are distinguished by much greater richness of ornamentation, but in its development English architects seem to have been restrained by marked sobriety of taste as compared with those of France and Germany. In England Gothic architecture must be regarded as having reached its most perfect form during this period: the succeeding period was one of decline. In France and Germany there was already some loss of purity, though the full flow of extravagance and debasement did not occur till the next century. As in the previous style, the windows and vaulting are the distinguishing features. There was little difference in the arrangements of the buildings, except perhaps that symbolism was more regarded. The vaulting is more subdivided into cells than that of the previous period, by the addition of intermediate ribs intersecting each other so as to produce a kind of tracery consisting of stars and other figures whereby much variety and richness are obtained. Richly carved bosses occur also at the intersections of the ribs. Some of these groined roofs are very beautiful; those of choirs are generally more elaborate than those of naves. Of the open wooden roofs of this period, not many examples remain.

Of windows a no less instructive than beautiful transition illustration is afforded by those of York Chapter-house, where we distinctly behold the progress to more complex geometrical tracery. The arch of the window is still of the lancet form, and highly pointed, being extracentred about two-thirds of its span; and the increased degree of enrichment is produced, not by the introduction of new elements, but by repeating and combining those previously in use. Thus the foliated or cusped circle continued to be the chief member decorating the head of the window, being merely tripled in number, an arrangement which accords beautifully with the triangular outline of the space so occupied; at the same time that these circular divisions contrast agreeably with the acute form of the arch, and soften its asperity. In like manner the multiplied divisions in the lower part of the window are produced by merely putting together two arched compartments with circles in their heads, similar to the example already given from Westminster, with a narrower one between them; thus forming the whole lower space into five narrow compartments, each of which has its own arch. In these lesser arches, which are simply cusped, and so far differ from those in the first example, we see the commencement of trefoil and cinquefoil ones; while in their shafts we plainly recognise mullions, which were afterwards of general application, either of uniform dimensions, or, in larger windows, consisting of principal and secondary ones. When the arch became equilateral, or nearly so, the tracery also assumed a different character, becoming of that kind which is called geometrical, and consisting of more varied forms and patterns, produced by circles, portions of circles, and other curves, enriched with cusps, dividing the spaces into foils. Of such windows we give examples from one at Exeter, and another at Kirton Church, Lincolnshire. This distinction between tracery by geometrical figures (circles, triangles, &c.) as shown in the first of these examples, and that formed by flowing curves as in the second, is observed throughout the window tracery of the earlier and later parts of the Second Pointed style: hence it has been proposed to subdivide it into the Geometrical and Curvilinear, or Geometrical and

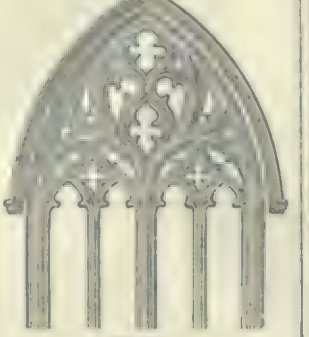


From York Chapter-house.

Complete Middle Pointed; the dividing line being variously fixed about 1315 and 1330.



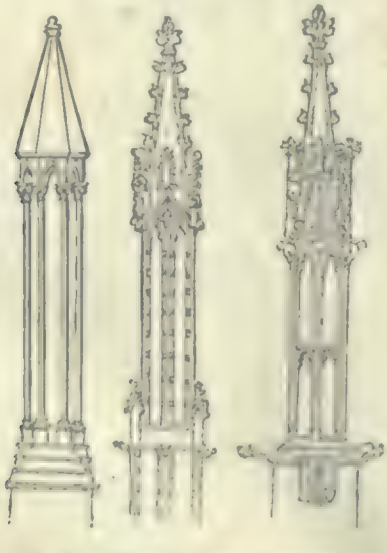
Exeter.



Kirton.

In the first of the examples given above, the pattern is formed chiefly by a single large circle subdivided into three spherical triangles sixfoiled, and three lesser ones trefoiled; to which minutiæ we call attention in order that the reader may be led to examine the figure attentively, and thereby learn, without further explanation, what is meant by those terms, and by *foils* and *cusps* generally. He will here further observe that small shafts and capitals have given way to mullions as dividing the lights, although retained at the sides of the window. The other example differs from the one just spoken of, not only in its tracery, which is more playful and flowing, but in having two orders of mullions, that in the centre, or the principal mullion, being thicker, and composed of more mouldings than the secondary ones. It deserves also to be remarked, that here the number of the open spaces, or lights, as they are termed, is even, and that of the mullions uneven; whereas in the other and the preceding figure the lights are uneven, and the mullions even in number; a circumstance quite independent of style, since either mode is followed according as it best suits the design for, and principal divisions of, the window-head. Of what is called geometrical tracery numerous specimens occur in the rich west front of York Cathedral, finished about 1330.

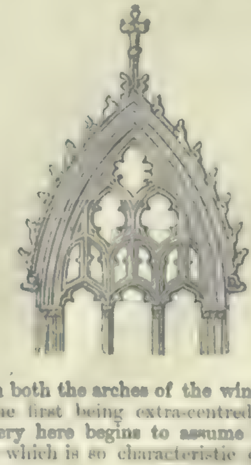
As mullions began to be substituted for pillars or shafts in windows, so too, both in the splays of doorways and in arch piers, columns began to be incorporated with the main pier, or splay itself; and in smaller doorways the arch mouldings are frequently continued down vertically, without any indication of capital, or impost to the arches, and die away, as it is termed, into a sloping surface, at a short distance from the ground. The external projecting mouldings of the arch, called by some hood-mouldings, by others weather-mouldings, or dripstone, as serving to throw off the droppings of rain, usually rest on corbels cut into the forms of heads. In many instances these hood-mouldings, both of doors and windows, are surmounted by other mouldings, forming a kind of gable, distinguished by the name of canopy. These canopies are generally enriched with crockets, small leaf-like ornaments, placed at intervals on the outer edge, which were first introduced, but used much more sparingly during the First Pointed period. The pediment heads to the different stages of buttresses are often similarly decorated. In conformity with the rest, greater ornament was likewise bestowed upon pinnacles, as will be seen on comparing a specimen of First Pointed character, from Wells Cathedral, with two others belonging to the Second Pointed style, the first from St. Mary's, Oxford, the other from York.

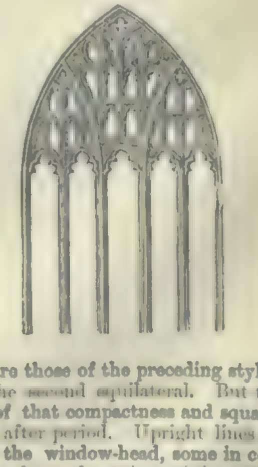


Doorways of the Second Pointed style are in the more important buildings often very richly sculptured. The shafts are thin, the capitals have the characteristic freely carved foliage; the jambs are finished with crocketed canopies, and small statues occupy narrow niches; the mouldings are enriched with ball flowers, foliage, &c.; the weather-moulding is supported by corbels carved as heads, or by bosses of foliage, and is terminated by a finial; and where the opening is wide it is sometimes divided by clustered shafts, as at the chapter house of York minster. Some of the earlier doorways are narrow, and resemble those of the First Pointed period, but are less deeply recessed,—a distinction maintained throughout the period. Stone porches are not infrequent; they are often large, richly sculptured, and in some instances have a room over them. The buttresses of this style are much more varied than in the First Pointed; flying buttresses are frequent, and of excellent outline and proportions. Parapets are either pierced or panelled, and sometimes embattled. Columns are in the plainer churches cylindrical or octagonal; but in those of a superior class they consist of clustered half or three-quarter cylindrical attached shafts, sometimes set lozenge-wise on the plan. Their bases are somewhat peculiar; in plan they sometimes differ from the shafts, and they are formed by a series of mouldings. The capitals usually, but not invariably, agree with the form of the shafts, and have fillet ogee or other cap-mouldings. In larger churches the capitals are enriched with foliage, sharply and often admirably carved, and sometimes seemingly direct from nature. The abacus is less prominent than in First Pointed capitals. Mouldings are very varied, and introduced with great effect, but it is quite impossible to particularise them. They will be found amply described and illustrated in Mr. Paley's 'Gothic Mouldings,' and other works which treat of the details of Gothic architecture. As a useful generalisation,—not to be received as an invariable law,—we may quote Mr. Paley's broad discrimination of the mouldings of the three periods: "It may be stated as a principle, that First Pointed mouldings exhibit a predominance of concave, Middle Pointed of convex, Third Pointed of sharp-edged members." As characteristic examples of this style may be mentioned the choir of Lincoln cathedral (1324); the nave and the west front of York Minster (completed 1330); the lady chapel and choir of Ely; parts of Lichfield, Bristol, Worcester, Winchester, Norwich, Wells, Canterbury, and Carlisle cathedrals; the magnificent parish churches of Grantham, Boston, and Heckington, in Lincolnshire; Hingham, Norfolk; Howden, Yorkshire; Dorchester; Adderbury, Stanton-Harcourt, and Bloxham, Oxfordshire; Trumpington, Cambridgeshire; several of the churches of Northamptonshire; and many others to be found in every part of the country.

In France, as in England, the Gothic of the 14th century (Ogival secondaire) is distinguished from that of the 13th chiefly by an increase of sculptural ornamentation, the introduction of more elaborate window tracery, greater lightness and venturesomeness of construction, and altogether a greater solicitude for splendour of effect. But whilst in England this tendency was kept in check by sound judgment and great sobriety of taste, in France the architects permitted themselves to run into excess; and, despite their surpassing splendour and picturesqueness, even their best buildings exhibit a decline from the high standard of the preceding century. Among the more remarkable examples of this period are the churches of St. Ouen, Rouen, and St. Laurent au Puy, and parts of the cathedrals of Rouen, Tours, Amiens, Paris, Bayeux, Poitiers, Nevers, Narbonne, &c.

In order to exhibit the progress from this to the Third Pointed style, we give two transition specimens of windows from York choir, the first decidedly of a transition character.

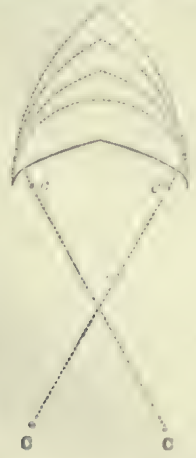




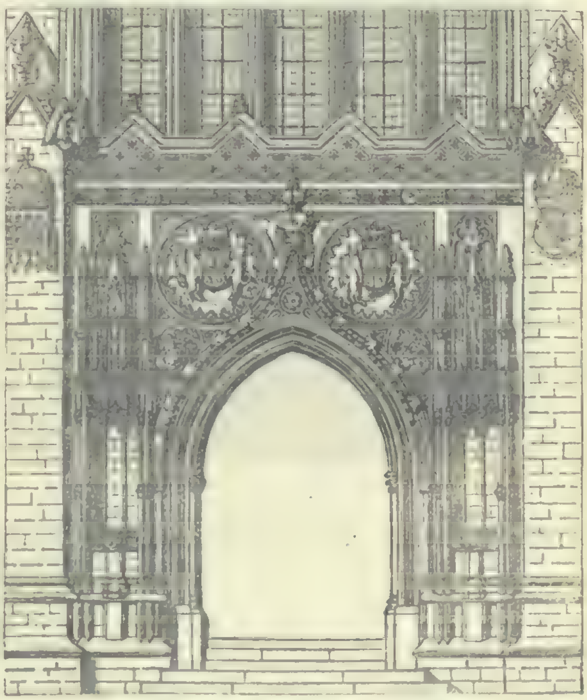
In both the arches of the windows are those of the preceding styles, in the first being extra-centred, in the second equilateral. But the tracery here begins to assume some of that compactness and squareness which is so characteristic of the after period. Upright lines or shorter mullions are introduced into the window-head, some in continuation of those below, others rising from the points of the arches which form the heads of the lower compartments; so that if we wished to express this circumstance by a single term we might employ the epithet *super-mullioned*, as indicating that the upper divisions of the windows have mullions rising from the arches of the lower ones. These two examples will further be useful, the first as supplying an example of *crockets* on the outer arch-moulding, and of a *finial* on its apex; the other as an instance in point, as respects what we have said of very acute arches being included in the tracery to windows whose arches are equilateral, or even much lower; for those which form the heads of the two compartments, each comprising two lights on either side of the centre one, are highly pointed, being extra-centred, and their height equal to $1\frac{2}{3}$ their span.

Of the Third Pointed, or Perpendicular, style, which may for convenience' sake be dated from 1400, and considered that of the 15th century, we must repeat that although the name Perpendicular, first bestowed on it by Rickman, and since very commonly adopted, appears to be tolerably correct in some respects, it is objectionable, and indeed misleading, in others; because, if "the mullions of windows and the ornamental panellings run in perpendicular lines," it is no less obvious that the numerous transoms, square-headed labels to doorways, and ornamental string-courses and cornices, produce as many horizontal ones; consequently Horizontal would be an equally appropriate term; perhaps even the more appropriate of the two, since the mullions thus crossed by transoms do not exhibit that prevalence of perpendicular lines which mullions alone, or slender columns do. The same may be said in regard to labelled doorways, &c., where the pointed character produced by the arch in a great measure loses itself, and is exchanged for that marked by squareness of outline. Nay, in the later examples, the very form of the arch itself shows a tendency to horizontality, by becoming so flattened that the height is sometimes less than one-fourth of the span (whereas in the equilateral arch it exceeds that measure).

Windows of this period are of two classes, two or four-centred: the former belong to the earlier, the others to the later half of the continuance of the style. What at once distinguishes Third Pointed windows from those of the earlier styles, is the vertical bearing of the mullions. In First and Second Pointed examples the mullions diverge in the head of the windows into curves or flowing lines: in the Third Pointed they are carried straight up till they cut the enclosing arch, while smaller divergent and upright mullions and transoms divide the head into smaller arched and panel-like compartments. In some of the richer examples the transoms are *embattled*, or indented by being cut into small battlements. As to the variety displayed in the tracery of the windows, it is quite impossible to describe it, since almost every specimen exhibits a different pattern; its general character may however be understood from the second of the examples above given from York Cathedral. The depressed or four-centred arch is so characteristic of the latter portion of this period, that a few words may be well devoted to a more particular notice of it. By the annexed diagram it will be seen that the superior centres, *c c*, for the shorter radii describing the two quadrants at the spring of the arch, are upon the span-line itself; and the two inferior centres, C C, whose radii are in continuation of the others, describe the remaining curves meeting at the vertex of the arch. This compound form admits of great diversity, according to the proportion the shorter and longer radii bear to each other, or in other words, according as the centres are fixed. In order to exhibit at the same time a comparison of this kind of arch, both with the semicircular and the varieties of the two-centred one, we have enclosed it within dotted lines, representing the others in succession above it, by which it will be apparent that if the span be the same, the extra-centred or lancet arch will be the highest, next to that the other two-centred arches, then the semicircular one, and lastly the compound or four-centred arch. But if, on the contrary, they were all made equal in height, the order of precedency would then be reversed, for the four-centred one would be the widest, and the lancet the narrowest, as has already been partially exemplified in a preceding diagram. Examples of this compound arch occur in French buildings of the latter part of the 15th century, but so rarely that it may be regarded as almost peculiar to England. From its frequent occurrence in the buildings of the close of the 15th and first half of the 16th century, it is commonly known as the Tudor arch.



Of Doorways the outline became square, owing to the arch being inclosed within mouldings forming what is called a *label*, which generally terminated at the spring of the arch, where it either rested upon corbels in the form of shields or heads, or was else bent and returned horizontally for about double the breadth of the other mouldings. The triangular spaces or *spandrels* thus formed between the curved mouldings of the arch and the square ones of the label are mostly filled up with quatrefoil circles or other decoration. In the larger and richer kind of doorways, as in the porch of King's College Chapel, Cambridge, the spandrels are greatly enlarged by the head of the square panel or compartment in which the arch is placed being carried up much higher. In this example there is an ogee canopy formed by what are called mouldings of *contrary flexure;* and this is crocketed and surmounted by a finial. Although this specimen, which has been selected as a beautiful instance of the Third Pointed style, does not exhibit the four-centred, or compound arch, it should be remarked that the latter characterises the other parts of the edifice. In the architraves or mouldings along the sides of doors and windows there are generally one or more large hollows, which may be taken as one of the marks of this style.

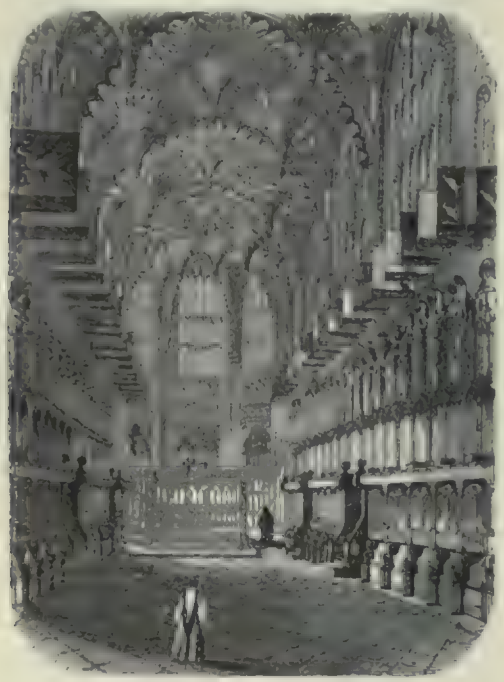


Doorway, King's College Chapel, Cambridge.

Although they have not labels, both windows and pier arches are not unfrequently treated somewhat similarly, being placed within square-headed compartments, whose spandrels are filled up with tracery resembling that of the window; which practice, no doubt, afterwards led to that of square-headed windows, by perforating the whole compartment, and making the spandrels part of the window itself. Windows placed within compartments, with spandrels of blank tracery, may be seen in the clerestory of Henry VII.'s chapel.

Hitherto we have spoken chiefly of arches and windows, but we must now briefly advert to the roof, at least to one species of vaulting used for it, peculiar to the richer examples of this style, we mean that consisting of *fan-tracery*, so called from the numerous small ribs or mouldings spreading out from the spring of the groining as from a stem, and radiating so as to describe a semicircle, the fan on one side meeting that on the other, in the centre of the vaulting; whereby a spandrel with four convex curves for its sides is left between two opposite pairs, and this space is either filled with tracery arranged so as to form a circle, or else is occupied by what is called a *fan-pendent*, similar to the other fans, except that its base on the ceiling is an entire circle instead of a semicircle. Of fan-groining with enriched spandrels only, the cloisters of St. Stephen's chapel, Westminster, offered a beautiful example; and of that with pendents, the chapels of King's College, Cambridge, and Henry VII., Westminster. The two structures just mentioned and St. George's chapel, Windsor, are in every respect perfect examples of this style, being of uniform design throughout, without intermixture of any other. Examples of the plainer vaulted roofs occur in the nave of Winchester cathedral, the nave and choir of Norwich, the choirs of Gloucester and Oxford, and the

Beauchamp chapel, Warwick. The open wooden roofs of this period are also characteristic, and sometimes extremely fine: that of Westminster Hall is one of the most striking. Brandon's 'Open Timber Roofs of the Middle Ages,' 4to, 1849, supplies ample particulars and illustrations of them. Usually the roofs of this period are of much lower pitch than those of the preceding styles. The external roofs of Henry the VII.'s and King's College chapels, for example, are so low in pitch as not to be visible from the ground, being concealed by the elaborate pierced parapets which crown the walls. These pierced parapets form a noticeable feature of the buildings of this period, and often afford very graceful terminations to the structure; but embattled parapets are also common.



Henry VII.'s Chapel, Westminster.

A characteristic feature of this style is the panelling, or panel-work tracery, formed like that of the windows by mullions and transoms, with which both the internal and external walls are sometimes almost entirely covered. Henry VII.'s chapel, Westminster, affords a good example of perpendicular panelling. Stone porches are now numerous; they are often of large size, much enriched with panelling, and canopied niches for statuary, and have handsome groined roofs; the south-west porch of Canterbury cathedral. The south porches of Gloucester cathedral; St. Nicholas chapel, Lynn; Northleach church, Gloucestershire; Addlethorpe church, Lincolnshire; Burford church, Oxfordshire; and Oundle, Northamptonshire, are rich and elegant examples. The church towers during this period are important and characteristic. They are frequently very lofty and much enriched with panelling. Perhaps the finest is that of Gloucester cathedral, erected about 1445; it rises to a height of upwards of 200 feet in two stories, has its surface covered with panelling, and is crowned with four pinnacles at the angles, of extremely light and elegant design. Two celebrated towers of this date were those of Doncaster church, now replaced by a recently erected one of a different character, and of St. Mary's, Taunton, now in course of restoration. Several other west country towers, as St. Stephen's, Bristol; Cirencester, Glastonbury, &c. are fine examples of the style. One of the best towers of late date is that of Magdalen College, Oxford. The towers are not usually surmounted with spires, but there are many spires of this date, and some are of a very elaborate and ornamental character; that of St. Nicholas, Newcastle, is a well-known instance. The buttresses, both of the ordinary kind and flying buttresses, are often of remarkable projection and highly enriched: some illustrations of them are given under BUTTRESS.

In the later examples of the Third Pointed, there is a great excess of ornament, and a constantly increasing deterioration of taste. But so long as the Gothic spirit was retained, in fact till that debased style commonly known as the Tudor was thoroughly established, the English Third Pointed buildings were vastly superior to the contemporaneous Gothic edifices of the continent. As Mr. Willis observes in his admirable 'Remarks on the Architecture of the Middle Ages,' "The Perpendicular is our own, and heartily may we congratulate ourselves upon it, when we compare it with its sister styles of France and Germany."

During its later stages the Third Pointed architecture was greatly more extended, both in its uses and modifications, than the two previous styles, having been applied to domestic as well as ecclesiastical architecture; whereas we are acquainted with the preceding styles only as it was employed in religious buildings; for castellated ones of the same periods have so little in common with the former, and so very few features wherein the general style at all exhibits itself, that they must be considered as forming a distinct class by themselves. In the ornamented domestic architecture of the 15th and early part of the 16th centuries, we plainly perceive the same style as that of ecclesiastical buildings applied to another class, where, although the parts are on a smaller scale and somewhat differently composed, the style of detail and ornament is essentially the same. While some features, such as doors and porches, are very little altered from those of churches, others unknown to the latter class of buildings, such as bay-windows and oriels, chimneys, &c., become highly characteristic and decorative in this. But this domestic architecture only became fully developed as the ecclesiastical was decaying, and hence it is generally spoken of as *Tudor Architecture*. In the reign of Henry VIII. a classic bias began to gain ground in England, as it had some time before spread through the continent; and before it the Gothic spirit paled, and eventually disappeared. At first a few, then gradually more and more, of imitative classic details were mingled with the native forms, until at last resulted that style which in its essence corresponded to what on the continent was known as the RENAISSANCE. Some few and feeble attempts were made to build in the Pointed style as late as the 17th century, but they only served to show how entirely the feeling for what was characteristic of it had departed.

Besides the buildings already referred to, the following may be named as illustrative of the art of this period:—Winchester cathedral, and New College, Oxford, the work of William of Wykeham; the nave of Ripon cathedral; Chester cathedral, and parts of Canterbury, Bristol, Worcester, Wells, and Oxford cathedrals; the Divinity Schools, and several of the colleges, of Oxford and Cambridge; St. George's chapel, Windsor; Eton College chapel; and Redcliffe (Bristol), Beverley, Rotherham, Taunton, Cirencester, Stratford-upon-Avon, and a vast number of other parish churches.

The style Ogival Tertiaire of France is characterised even more than the English Third Pointed by excess of florid ornamentation, which went on increasing till the abandonment of the style for the Renaissance, in the 16th century. It differs in not being characterised by the same tendency to rectilineal lines; though towards the close of the 15th century, panelling, similar in character to the English, was often, though less profusely, employed. The characteristic window tracery is of the lambent flame-like kind from which the style has received its popular title—the *Flamboyant*. The roof vaulting is ramified; in later examples the depressed arch is frequent in doorways. Towers with open spires, often of a degree of lightness quite astonishing in stonework, are seen in churches of a superior class, as at Amiens. The outline and surface are cut up by a crowd of carved foliage, and all kinds of petty ornamentation; but the carving, looked at alone, is often admirably executed. Altogether the buildings show a marked loss of grandeur and purity; but many of them are triumphs of constructive ingenuity. Their builders sought to excite the astonishment of the spectators, and they succeeded. Very fine examples of this style are the churches of St Nisier at Lyon, Pont l'Evêque, Caudebec, Louvois, the cathedral of St. Brieux, &c.

The German architects of the 15th century ran into still greater extravagances than the French; but for notices of the later developments of German Gothic, as well as for that of the Netherlands and Italy (a subject that has lately excited a good deal of attention), we must refer to the works cited below. Here we shall merely add, by way of conclusion, a brief summary of a few of the more prominent distinctions between Grecian and Gothic architecture, as regards the application of their respective elements. *Grecian*: Columns and their entablature are the chief sources of decoration, and limit the height of the building, as a second order cannot with propriety be placed above another. *Gothic:* Columns subordinate members; never used except to support arches, and in the latter styles are mere ornamental shafts attached to piers. *Grecian:* Colonnades seldom employed except externally. *Gothic:* Ranges of open arches applied only internally; there being nothing analogous to a Grecian portico, since porches have merely an open arch in front, and when projecting from the building are closed at the sides. Externally, open arcades are introduced only as upper galleries, and those are of very rare occurrence; or, as a cloister, not projecting from but within the lower part of the building. *Grecian:* Lofty proportions unattainable even in the largest edifices, because the greater the number of columns the lower will the building appear in comparison with its length or breadth. *Gothic:* No restraint as to loftiness, that not being regulated by width even of the whole front or any of its parts. *Grecian:* The pitch of a pediment must be governed by its span, since its height must in no case greatly exceed the depth of the entablature; consequently, the greater the number of columns placed beneath it, the lower it must be, and the lower the proportions of the whole front. *Gothic:* Gables may be of any pitch, just as best accords with construction or the composition of the design. *Grecian:* Little variety of form and proportions in doors or windows, or in regard to their external mouldings; the window itself a mere aperture, without any architectural filling up. *Gothic:* Both doorways and windows very conspicuous features, admitting the utmost diversity, as well in their forms and proportions as in the modes of decorating them.

Windows especially admit of innumerable combinations in regard to their divisions and the ornamental tracery within their arched heads. The same remark applies to the panelling of doors. *Grecian:* All mouldings and other decorative members project from the face of the wall. *Gothic:* All but what are termed weather-mouldings retire within the face of the wall. *Grecian:* No splayed surfaces. *Gothic:* Sloping or splayed surfaces, both horizontal and vertical, very prevalent; in fact, windows and doors are universally placed within splays, more or less deep, and enriched with various mouldings. *Grecian:* No concave mouldings or deep hollows. *Gothic:* Deep hollows of this kind enter into almost every combination of mouldings, whether horizontal or perpendicular.

The most useful general view of English Gothic for the ordinary reader is Mr. Bloxam's excellent little volume, 'The Principles of Gothic Ecclesiastical Architecture,' 10th ed., 1859. For French and German Gothic, a similar survey will be afforded by De Caumont's 'Architecture Réligieuse,' 3rd ed., 1854; and H. Otto's 'Handbuch der Kirchlichen Kunst-Archæologie des Deutschen Mittelalters,' 3rd ed. 1854. Mr. Fergusson's valuable 'Illustrated Handbook of Architecture' affords a broad summary of the characteristics of all the schools of Gothic architecture. Those who wish to carry their investigations deeper will find great assistance in the following works, which, however, are but a very few of the many elaborate works on mediæval architecture published within the last few years:—Gailhabaud, 'Monuments Anciens et Moderns,' and 'L'Architecture du Ve au XVI^e^ Siècle,' 4to, 1851; Chapuy, 'Moyen Age Monumental;' L. Drouyn, 'Architecture au Moyen Age;' Viollet le Duc, 'Dictionnaire raisonné de l'Architecture Française du XI^e^ au XVI^e^ Siècle;' Bourassé, 'Les Cathedrals de France;' A. Lenoir, 'Architecture Monastique;' F. Stroobant, 'Monuments d'Architecture, &c., en Belgique,' 4to, 1852; J. L. Petit, 'Architectural Studies in France,' 1854; Whewell, 'Architectural Notes on German Churches,' 3rd ed.; G. Moller, 'Denkmäler der Deutschen Baukunst' (fol.), the text published in England under the title of 'Memorials of German Gothic Architecture, translated by W. H. Leeds;' G. G. Von Kallenbach, 'Atlas zur Geschichte der Deutsch-Mittelalterlichen Baukunst,' fol., 1847; Boisserée, 'Denkmale der Baukunst vom 7ten bis zum 13ten Jahrhundert am Nieder Rhin,' fol., 1833; Springer, 'Die Baukunst des Christlichen Mittelalters,' 8vo, 1854; Gally Knight, 'The Ecclesiastical Architecture of Italy;' Cresy and Taylor, 'Architecture of the Middle Ages in Italy;' Street, 'Brick and Marble Architecture of Italy in the Middle Ages;' Ruskin, 'Seven Lamps of Architecture,' and 'Stones of Venice;' Willis, 'Remarks on the Architecture of the Middle Ages;' A. F. Von Minutoli, 'Der Dom zu Drontheim, und die Mittelalterliche Christliche Baukunst der Scandinavischen Normannen,' fol., 1853; Brandon's 'Analysis of Gothic Architecture;' Garbett's 'Rudimentary Treatise on Design;' and the works of Rickman, Britton, Pugin, Paley, Sharpe, Freeman, &c., with the illustrations of the cathedrals, &c., by Carter, Winkles, Le Keux, &c.

GOTHIC LANGUAGE. It is now generally admitted that the Gothic language or languages is or are a branch of the Teutonic family. (J. Grimm, 'Deutsche Grammatik,' and H. Meidinger, 'Vergleichendes Etymologisches Wörterbuch der Gothisch-Teutonisch Mundarten,' 8vo., Frankfort on-the-Main, 1833.) The Altgotisch, or old Gothic, was the language of the Goths who lived near the banks of the Lower Danube in the 4th century, and for whom Ulfilas made a translation of the Gospels, of which the greater part exists in the silver book preserved in the library of Upsala. [ARGENTEUS CODEX.] Ulfilas was bishop of those Goths who lived in Mœsia in the time of the Emperor Valens, and the language of his version has been styled Mœso-Gothic. He is believed to have invented the characters employed in the version, and which are formed, with slight variations, from the Greek and Latin capitals. [ALPHABET.] This and a few other fragments, chiefly scriptural, of about the same age, are all the remains of a language once spoken by the West-Goths, or Visigoths of Spain, and the Eastern Goths of Hungary and Italy. It had five vowels, and four dipthongs, ai, au, ei, and iu; and the conjugations were even more complete than the present Swedish. Another branch of the Gothic or Gotho-Teutonic language existed in Scandinavia, which German philologists have called Altnordisch, or old Norse, and in which the 'Edda' is written, and which is still spoken with some variations in Iceland, the Faroe Islands and parts of Norway. (Meidinger). Out of this language the modern Swedish, Danish, and Norwegian sprung. Inscriptions in the old Norse, or Scandinavian Gothic, have been found in several parts of Sweden, Denmark, and in the island of Gothland, in various characters different from those of Ulfilas's Mœso-Gothic versions. Bonaventura Vulcanius, the editor of Jornandes' 'De rebus Geticis,' published also an anonymous treatise on the Gothic language; 'Commentariolum Viri cujusdam docti anonymi in Literas Gothicas,' with specimens of the Mœso-Gothic, old high German, Anglo-Saxon, and other old Teutonic dialects, followed by four different Scandinavian Gothic alphabets collected from various inscriptions, and one of which is similar to the one given by Magnus in his 'Historia Gothorum Sueonumque,' b. i. ch. 7. The old Scandinavian, or Norse, or Suio-Gôthic, is considered by Adelung as being a mixture of Gothic with the language of the Sveones, the original inhabitants of the Scandinavian peninsula, previous to the Gothic immigration, and the modern Swedish, which is derived from the old Scandinavian, appears to have elements in it foreign to the Teutonic, though the Teutonic, or Gothic, greatly prevails in both.

(Petersen, *Det Danske, Norske, og Svenske Sprogs Historie*, Copenhagen, 2 vols. 8vo., 1830.)

GOTHS, GOTHI, GOTHONES, a powerful northern nation who acted an important part in the overthrow of the Roman empire. Tacitus ('German.') mentions the Gothones as a German tribe, dwelling between the Lygians and the Rugians and Lemovians, the last two possessing the shores of the Baltic, while he considers the Gothini, who lived in Southern Germany, as a tribe of Celts, or Gauls. Ptolemy calls them Gothunes, considers them to be a Sarmatian tribe, and places them south of the Wends, and eastward of the Vistula.

About the middle of the 3rd century the Goths are recorded to have crossed the Dniester and to have devastated Dacia and Thrace. The emperor Decius lost his life in opposing them in Mœsia, A.D. 251, after which his successor, Gallus, induced them by money to withdraw again to their old dwellings on the Dniester. They then seem to have spread eastwards, and to have occupied the country about the Cimmerian Bosphorus, from whence they sailed across the Euxine, occupied Trebisond, and ravaged Bithynia. In the year 269 they landed in Macedonia, but were defeated by the emperor Claudius II. Three years after, Aurelian gave up Dacia to a tribe of Goths, who are believed to be the Visigoths, or Western Goths, while those who ravaged Asia Minor were the Eastern Goths, or Ostrogoths. This distinction of the race into two grand divisions appears about this time. Under Constantine I. the Goths from Dacia invaded Illyricum, but were repelled; afterwards Constantine II. allowed a part of them to settle in Mœsia, who seem to have soon after embraced Christianity, as it was for them that Ulfilas translated the Scriptures, about the middle of the 4th century, into the dialect called Mœso-Gothic. [GOTHIC LANGUAGE.] About the year 375, the Huns, coming from the east, fell upon the Ostrogoths, and drove them upon the Visigoths, who were living north of the Danube. The latter, being hard pressed, implored permission of the Roman commander to be allowed to cross that river, and take shelter on the territory of the empire. The Emperor Valens consented, and a vast multitude of them were allowed to settle in Mœsia; but soon afterwards they quarrelled with the Roman authorities, invaded Thrace, and defeated and killed Valens, who came to oppose them. From that time they exercised great influence over the Byzantine court, either as allies and mercenaries, or as formidable enemies. Towards the end of the 4th century, Alaric, being chosen king of the Visigoths, invaded North Italy, but was defeated by Stilicho near Verona. He came again, however, a few years after, and took and plundered Rome. His successor, Ataulphus, made peace with the Empire, and repaired to the south of Gaul, where the Visigoths founded a kingdom, from which they afterwards passed into Spain, where a Visigothic dynasty reigned for more than two centuries, till it was conquered by the Moors. Meantime the Ostrogoths, or Eastern Goths, who had settled in Pannonia after the destruction of the kingdom of the Huns, extended their dominion over Noricum, Rhætia, and the Illyricum; about the year 489, they invaded Italy under their king Theodoric, and defeated Odoacer, chief of the Heruli, who had assumed the title of king of Italy, a title which Theodoric then took for himself with the consent of the Eastern emperor. Theodoric was a great prince: his reign was a period of rest for Italy, and his wise administration did much towards healing the wounds of that country. But his successors degenerated, and the Gothic dominion over Italy lasted only till 554, when it was overthrown by Narses, the general of Justinian. From that time the Goths figure no longer as a power in the history of Western Europe, except in Spain. We find however their name perpetuated long after in Scandinavia, where they probably arrived from some country east of the Vistula, or even as the Icelandic traditions assert, from the neighbourhood of the Caspian sea, at some time preceding that of their moving southward. A kingdom of Gothia existed till the 12th century distinct from Sweden Proper, until both crowns were united on the head of Charles Swerkerson, in the year 1161, who assumed the title of king of the Swedes and the Goths, which his successors bear to this day.

GOUT (*gutta*, a drop). This name was given to the disease which we are about to describe, from a fanciful notion that it arose from some morbid matter, deposited by drops in the joints. In technical language gout is called *Arthritis* or *Podagra*. It may be defined to be an inflammatory affection of the joints, arising from a morbid action in the system. It is mostly an hereditary disease, coming on without any evident external cause, generally preceded by disorder of the digestive organs, and accompanied by a plethoric state of the system. The inflammation attacks the smaller joints, particularly the first joint of the great toe, and returns at intervals, various joints or parts becoming affected after repeated attacks.

A paroxysm of gout is generally preceded by some constitutional disturbance, though it may attack a person suddenly who is apparently in good health. It is commonly ushered in by a disordered state of the whole system; both the circulating, nervous, digestive, and secreting organs are out of order. The pulse is frequent and full; there is a feeling of repletion and oppression; drowsiness or restlessness; general lassitude and depression of spirits; flatulence; irregular appetite; costiveness; and high coloured urine, which deposits a pink sediment on cooling. The local affection generally commences suddenly in the middle of the night. The patient is awakened at two or three o'clock in the morning with acute pain in the ball of the great toe, accompanied with a feeling of heat and stiffness of the part: chilliness and fever come on, which gradually abate as the pain increases, which becomes more violent every hour, having a burning or gnawing character. This generally continues till the middle of the following night, though in slight cases it may remit after a few hours' duration. A gentle perspiration then breaks out, and the patient falls asleep. The next morning the toe is shining, red, and swelled; the veins of the foot are very much distended, and the joint is excessively tender. Exacerbations, becoming less violent each time, recur for several nights, and then the attack declines. The joint remains swelled and weak for some days, and there is violent itching, followed by desquamation of the cuticle; after which all disease ceases, and the patient feels better, both in body and mind, than before the attack.

Such are the history and course of a simple fit of gout, as it generally occurs on its first attack. In subsequent seizures, the inflammation, on subsiding in one joint, frequently attacks another, and eventually several joints may be attacked in succession, or two or more at the same time, as the fingers, wrists, and knees. Generally the intervals between the attacks grow shorter, the patient has more and more frequent fits, and they last longer; but this will depend in a great measure on the treatment pursued, and the mode of life of the patient. The fits are more liable to occur in the spring and autumn than at other seasons, owing perhaps to the greater variableness of the weather at those times of the year. After repeated attacks the joints may become stiff and rigid: deposits of whitish matter, called chalk-stones [Calculi] (which principally consist of urate of soda), will take place beneath the skin, so that the joints of the fingers and toes become enlarged and swollen.

It is very common, when persons have had gout for a length of time, for various internal organs to become diseased. The inflammation may suddenly disappear from a joint, and some serious internal affection, as apoplexy or gastritis, unexpectedly make its appearance. This is called retrocedent or displaced gout. The internal affections which thus arise are often caused by the patient's imprudence, and sometimes by injudicious treatment, as the application of cold to the inflamed joint.

We have mentioned among the precursory symptoms of an attack of gout, that the urine is frequently turbid, and deposits a lateritious sediment. There seems to be a tendency to throw off morbid matter from the overloaded system by this outlet. It has been said that gout favours the formation of urinary calculi, and numerous cases are related where stone in the bladder, or gravel, has occurred in connection with this disease. Irritation of the urinary organs is certainly very common in gouty persons.

Gout is more frequently met with in persons of vigorous and robust constitutions, than in those of spare habit; and is more common in men than in women: this comparative immunity of the female sex seems to be owing in a great measure to their more temperate habits of life. Persons of advanced and middle age are more liable to gout than those of early life. It does not commonly appear till after the age of thirty-five, though where the predisposition is strong it may occur even before puberty. Hereditary predisposition is doubtless a cause of gout, and where this tendency exists the disease may take place under circumstances which would not otherwise have power to produce it. Hence persons who are conscious of an hereditary taint should guard with particular care against the causes which excite gouty action. The most active of these is a plethoric or inflammatory state of constitution, arising from luxurious living, indolence, and sedentary habits; which also give rise to that disordered state of the digestive organs which constantly precedes an attack of gout.

Where the predisposition, both hereditary and acquired, strongly exists, a very slight cause may excite the paroxysm. A fit of intemperance, or excessive indulgence in eating, may bring it on. Excitement of mind from anxiety or intense study will sometimes cause a fit of gout; and it has been known to follow violent exercise, particularly walking. An accident or injury of a joint, occurring in a gouty subject, instead of causing simple inflammation, may give rise to an attack of gout. Gout possesses a considerable resemblance in many of its characters to rheumatism, and these affections are in some instances confounded together. There are even modifications which partake so much of the characters of both, that they go by the name of rheumatic gout. Gout however may generally be known from rheumatism, by its attacking persons later advanced in life and of a full habit; by its affecting principally the smaller joints, and being commonly confined to one, at least in its earlier seizures; the attack of gout also declines more quickly, is preceded in most cases by disorder of the digestive organs, and is not brought on by any external exciting cause, as cold and damp, which is mostly the case in rheumatism.

With regard to the cause of gout, and the state of the system in which it comes on, considerable light has been thrown upon them by the researches of Dr. Garrod. He has shown that the retention of uric acid in the blood is the first of a series of changes, which results in the deposition of urate of soda in the joints or other parts affected with the gouty inflammation. The following are the conclusions at which Dr. Garrod has arrived and which he has published in his work 'On the Nature and Treatment of Gout.'

First. In true gout, uric acid is invariably present in the blood in abnormal quantities in the form of urate of soda.

Secondly. True gouty inflammation is always accompanied with a deposition of urate of soda in the inflamed part.

Thirdly. The deposit of urate of soda is crystalline and interstitial, and when once the cartilages and ligamentary structures become infiltrated, such deposition remains for a lengthened time, perhaps during life.

Fourthly. These deposits are the cause and not the effect of gouty inflammation.

Fifthly. The attack of gouty inflammation tends to destroy the urate of soda in the blood of the part, and in the system generally.

Sixthly. The kidneys are early implicated in gout, and this affection is not only functional, but eventually becomes structural. The urine in gout is always altered in composition.

Seventhly. The presence of urate of soda in the blood, is probably the cause of the premonitory symptoms of an attack of the gout, and of the anomalous symptoms which are known to present themselves in gouty subjects.

Eighthly. The causes known to predispose to the gouty attack are such as produce an increased formation of uric acid in the system, or which leads to its retention in the blood.

Ninthly. The causes exciting a fit of the gout are those which reduce the alkalinity of the blood, or augment the formation of uric acid, or temporarily check the power of the kidneys in eliminating this principle.

Dr. Garrod's theory has certainly the merit of explaining the anomalies presented in the history of gout. It shows that the tendency of the kidneys to refuse the elimination of uric acid may be hereditary, and it also explains that in poor systems, as well as plethoric ones, this tendency of the kidneys may serve to bring on an attack of gout.

The occurrence of a paroxysm of gout often seems to relieve the general health for a time; and it is a common idea that an attack expels the morbid matter from the system. Although this is true to a certain extent, it is a dangerous doctrine to put in practice. It has often led to very improper and even dangerous proceedings. On the contrary, the judicious plan of treatment in gout is to moderate the paroxysm and prevent its recurrence. It would be out of place here to enter into any detail of the numerous plans of treatment and the remedies which have been adopted in gout. With regard to the preventive treatment, we need only recommend temperance and exercise, which will generally succeed in keeping off a recurrence of the disease, and if strictly adopted will be a sufficient guidance to the gouty patient. There is an old Scotch proverb, and a very true one, "that a man might cure himself of gout by living on sixpence a day, and working for it." The treatment of the paroxysm is very simple. The inflammation should be subdued in this case by the same means as would be requisite in inflammation from any other cause. If the patient be plethoric, and there is active fever, we must bleed, purge, and starve him. Should there be less constitutional disturbance, we may safely leave the fit to run its course; for gouty inflammation has a natural tendency to subside spontaneously, without terminating in suppuration. Alkalies and saline medicines which act as purgatives and diuretics are also to be recommended. Dr. Garrod also recommends the salts of lithia.

Topical remedies are of little use in gout. Warm applications do no good, and cold ones may do serious harm by suddenly checking the inflammation, and bringing on dangerous affections of internal organs. If anything be applied to the part, a warm evaporating lotion is perhaps the best thing.

In addition to the general antiphlogistic treatment which we have mentioned, we possess a remedy which certainly is highly valuable in gout, namely, colchicum. This medicine, when given in a sufficient quantity, generally purges the bowels, and lowers the pulse. A large dose of this drug, given when the occurrence of a paroxysm is threatened, will often avert it altogether, but the prudence of this mode of proceeding is very questionable; it only suppresses the paroxysm, without removing the constitutional disorders on which the disease depends. Colchicum may be given with safety during a fit of gout, and it certainly seems to shorten its duration. The colchicum (of which the wine of the seeds is one of the best preparations) may be given, and repeated in moderate doses three or four times a day, either alone, or combined with purgatives. As soon as free purging is produced, the symptoms are generally relieved. Some authors are of opinion that the colchicum does no good without it acts upon the bowels; but in many instances, before this effect is produced, it will allay the pain, bring down the pulse, and stop the progress of the paroxysm. Colchicum is said to increase the secretion of uric acid by the kidneys, but this is denied by Dr. Garrod, who has carefully investigated the subject. This drug is the active ingredient in the *eau médicinale* and other quack medicines which are in general use as specifics for the cure of gout.

With respect to the treatment of the complex conditions and different varieties of gout, it must be directed to the improvement of that disordered state of constitution upon which they depend.

Persons of a gouty habit are liable to certain inflammatory affections of the eye (dependent on the state of the constitution), which differ in some respects from inflammation of the same parts arising from other causes. The external proper tunics, particularly the sclerotica, may be affected in the gouty; though in this case the iris generally participates in the inflammation. The sclerotica and conjunctiva may however be attacked without the iris in gouty persons; this affection is then similar to that modification of external ophthalmia which occurs more frequently from exposure to cold in persons who suffer from rheumatism, and is denominated rheumatic ophthalmia. [RHEUMATISM.]

Sometimes gouty inflammation of the sclerotica is accompanied with an erysipelatous form of inflammation of the conjunctiva. Beer has seen this follow the suppression of gout in the feet by cold.

Inflammation of the iris (arthritic iritis) is a much more common affection than the last in gouty persons, and is usually of an acute character. It commences with uneasy sensations in the eye, which are followed by pain about the orbit, forehead, and side of the head, and lastly in the eye itself. Redness of the sclerotica comes on, which is particularly seen round the cornea; attended with watering of the eye, and intolerance of light. The iris soon becomes dull and discoloured, the pupil is contracted, and fixed at one or more points to the capsule of the lens. It has been observed that the red zone round the cornea is less bright in this than in other forms of iritis [IRITIS]; and, as in rheumatic ophthalmia, does not quite extend to the cornea, but leaves a narrow white ring between them. This form of iritis often returns again and again, the eye recovering almost completely after repeated attacks. The iris however often becomes attached to the capsule of the lens by whitish adhesions, though without causing much injury to vision. Mr. Lawrence says that gouty inflammation, when severe and long-continued, sometimes causes complete disorganisation, with puckering, and tubercular projection of the iris, and extinction of sight. When arthritic iritis occurs in a person of plethoric habit, we must bleed and adopt general antiphlogistic treatment. Colchicum may also be given with advantage. Mercury seems to do more harm than good in this affection. The recurrence of the disease must be prevented by such means as remove the gouty disposition.

Besides the affections which we have described, persons of a gouty constitution are sometimes attacked with more extensive inflammation of the eye, affecting the internal parts of the globe generally; that is, the choroid membrane, iris, retina, vitreous humour, lens and its capsules, and secondarily involving the sclerotica and cornea. It generally ends in loss of sight, with a dilated pupil and opaque lens; but in some cases the latter change does not take place, and a green discoloration of the pupil remains: in this case, Mr. Lawrence calls the affection *acute glaucoma*. Arthritic inflammation of the internal tunics is a much more serious disease than gouty iritis, and almost invariably destroys sight. It is attended with great suffering; there is severe burning pain, which extends to the face and side of the head; and the eye itself feels distended, or swelled. There is redness of the sclerotica and conjunctiva; dulness of the cornea and iris; the pupillary margin of the latter is turned backwards, and the opening itself dilated and fixed. The lens becomes opaque, and often of a greenish colour, and is pushed forward into the dilated pupil; the eye loses its brilliancy and looks dead. The sight is lost at an early period of the disease. This disorder generally affects both the eyes in succession, and the most energetic treatment has hardly any effect upon it. Loss of blood, and other active measures, must be resorted to in the first stage of the affection. This disease is generally seen in elderly persons of full habit, with bloated red faces which are owing to indulgence in the pleasures of the table. These affections of the eye are sometimes due to rheumatic states of the system, which differ essentially from those of gout. [RHEUMATISM.]

GOVERNMENT is a word used in common speech in more than one sense. 1. It denotes the *act of governing*, as when we speak of "the business of government." 2. The *persons who govern* are, as often as not, called "the government;" and we thus speak of "the French government," "the Russian government," &c. 3. The word "government" is used elliptically for the phrase *form of government*, as when we speak of "a monarchical, aristocratical, or republican government;" or, again, of "the English or French government," meaning thereby the English or French form of government, or (changing the phrase) the English or French constitution.

The science of government, or the science which relates to the business of government, is more commonly called the science of legislation. So the art which flows from this science, or the art of governing, is called the art of legislation. In accordance, then, with the common phraseology, we shall now dismiss this first of the two sciences, and together with it that sense of the word "government" in which it signifies the act of governing; reserving them for treatment under the head LEGISLATION. In the present article we shall concern ourselves exclusively with that sense of the word "government" in which it stands for the phrase "form of government," confining ourselves to an enumeration of the various forms of government.

1. A government consists either of one person or of more than one.

When it consists of one person only, the appropriate name for the form of government would be *monarchy*. But we shall see hereafter that this name is generally, in common speech, fantastically bestowed on a particular class of governments of more than one; while a government of one only is called by the names of *absolute monarchy*, *despotism*, and *tyranny*. Of these three names, the last two may be objected to as names, because they always imply disapprobation, or because they are not only names, but also (to employ Mr. Bentham's phraseology) words dyslogistic. But the essence of this form of government is the complete dependence of the governed on the will of one person, which is well expressed by the terms despotism and tyranny; and the sense of disapprobation which hangs about these terms, or their dyslogistic character, is to be traced to the accidental circumstance of the conjugate terms *despotic and tyrannical* being commonly used to describe other forms of government, in which the arbitrary conduct of the governors resembles that of the generality of despots or tyrants.

2. A government of more than one may either consist of one homogeneous body, or (changing the phrase) of one body all whose members are appointed in the same way, or it may be mixed, compound, or consist of heterogeneous parts.

When the members of the one governing body, if hereditary, are a decided minority of the state, or, if deriving their powers from without their own body, they so derive them from a portion of the state which is yet a decided minority, the government is called by the names *aristocracy* and *oligarchy*. There is a difference in the use of these two terms which it is impossible to mark exactly. But it may be said roughly that the term oligarchy is used where the minority is very small, and the term aristocracy where it is not. The latter term also would be always employed where the members of the governing body derive their powers from without, or where the body is elective.

When, again, the members of the one governing body either themselves constitute, or derive their powers from, a portion of the state which is a decided majority, the government is called a *democracy*.

3. Before proceeding any further with that series of divisions, in which we have now taken two steps, we may remark that the three forms of government of which we have now spoken—namely, absolute monarchy or despotism, aristocracy or oligarchy, and democracy—are commonly called (as being governments of one person, or of one homogeneous body) pure forms of government, in contradistinction to the mixed forms which yet remain to be considered. The division of forms of government into pure and mixed is a complete division, which the common division into monarchy, aristocracy, and democracy, is not.

4. A mixed form of government is one compounded of the whole or of any two of the three elements which exist separately in the three pure forms of government, and also of individuals or bodies deriving their powers from different portions of the state, even though each of these different portions is a decided majority of the state. It is not necessary to enumerate all the mixed forms of government which arise from all the possible combinations. Besides that all the possible combinations may be easily seen, some of them produce forms of government which have never existed, and which consequently are no objects of interest. It will be sufficient, then, to speak of those combinations, or rather of those classes of combinations, with which men are familiar, and for which common speech supplies names.

The mixed forms of government which occur may be divided into two classes, according as an hereditary chief does or does not enter into their composition.

Governments which contain an hereditary chief united either with an aristocratic and a democratic body, or with an aristocratic body by itself, or with a democratic body by itself, are generally called *monarchies*. They are also called *limited monarchies*, as if to distinguish them from the governments of one only, to which, as we have said, the name monarchy more appropriately belongs, but to which, without the epithet *absolute* being prefixed, it is seldom or never applied.

As regards the governments of which an hereditary chief forms no part, it will be convenient to observe at the beginning, that the combinations of an elective chief with one or more democratic bodies are the only combinations which possess any interest for men; if, indeed, judging from the past, we may not also say that they are the only ones which are practicable. And having premised this, we may say that the governments into the composition of which an hereditary chief does not enter are generally called *republics*, or *representative governments* (the relation of the democratic body or bodies in the government to the portion or portions of the state that appoint them being known by the name representation), or, again, *pure representative governments*, as if to distinguish these from the forms of government in which a democratic body is united either with an hereditary chief and aristocratic body together, or with either of these by itself.

It is scarcely necessary for the objects of a Cyclopædia, which seeks to collect facts rather than to advance opinions, to enter upon the question of which is the best form of government.

GRACE, DAYS OF. [BILL OF EXCHANGE.]

GRACE. This word is frequently used in the Scriptures to denote in general the favour and love of God towards mankind, and also more particularly as manifested in the gift of his son Jesus Christ. (2 Cor. viii. 9.) It is also employed to designate that degree of divine influence upon the mind which enables an individual to believe in the Gospel. Grace is sometimes used in opposition to the law, and to express the happy condition of those who experience its benefits (Gal. v. 4, 5). Also the benefits themselves, or the gifts of the Holy Spirit (John i. 14, 16). Some theologians maintain that there are two kinds of grace, which they designate as *common* and *special;* the former consisting in such divine influences as operate beneficially upon the moral character, but leave the mind without real faith; the latter, which is necessary for salvation, being granted only to such individuals as have been elected to everlasting life. [ELECTION.] There is also difference of opinion among theologians on what is called *irresistible grace*, many considering "that grace may be resisted and rendered ineffectual by the perverse will of obstinate sinners;" while others believe "that it is never on the whole finally rejected, so as to fail working faith in those who are the happy subjects of it."

GRACES, GRA'TIÆ, or CHARITES, in ancient mythology, are represented as three young and handsome sisters, the attendants of Venus. Their names were Aglaia, Euphrosyne, and Thalia. Homer mentions but one Charis. The Lacedæmonians had only two, whom they called Kleta or Klyta, and Phaënne, and a temple in honour of them existed in the time of Pausanias between Sparta and Amyclæ (iii. 18; ix. 35). Hesiod, however, speaks of three. Some poets name Pasithea as one of the Graces. The idea of the Graces was, according to some, originally a symbolic personification: Aglaia represented the harmony and splendour of the creation, Euphrosyne represented cheerfulness and mirth, and Thalia feasts and dances. In short, they were an æsthetic conception of all that is beautiful and attractive in the physical as well as in the social world. Some called them the daughters of Zeus by Hera, Eurynome, Harmonia, or Lethe; others of Dionysus and Aphrodite; others, again, of Apollo and Enanthe. Their worship is said to have originated in Bœotia. They were originally represented as lightly clothed, but in latter times the sculptors made them entirely naked: they are usually figured holding each others hands or embracing, and bearing ears of corn or flowers. They were invoked to preside at the festive board, at nuptials, at births, &c. Their images were multiplied on an infinite number of sculptures, paintings, gems, and votive inscriptions were affixed to them. Groups of the three Graces have been found, forming one of the most pleasing representations of ancient art; and modern sculptors, Canova among the rest, have sought to rival the ancients in reproducing the same subject. (Millin; Hirt; Müller.)

GRADIENTS. [RAILWAY.]

GRADUATE. [ARTS, DEGREES IN.]

GRADUATION is the name commonly applied to the art of dividing mathematical and astronomical instruments. The nature of this work will not admit of a detailed account of the various methods and machines used in different branches of the art; we shall only give an outline of the different processes, with reference to the standard authorities, and add a few suggestions for the consideration of the astronomer and artist.

Graduation, or, as the workmen more generally style it, *dividing*, is performed in two ways, by making a *copy* of a system of divisions already existing, or by *original* dividing. The straight scales and rules which are in common use are divided thus:—The original pattern, and the scale on which the copy is to be laid, are placed side by side; a straight edge, with a shoulder at right angles, like a carpenter's square, is made to slide along the original, stopping at each division, when a corresponding stroke is cut by the dividing knife on the copy. With care and practice, this method admits of considerable accuracy. By making the straight edge turn on the centre of a divided circle, the divisions of that circle may be copied upon any concentric circle. Common protractors are thus divided, and scales upon circular limbs. The original circle, which may have several orders of divisions for different purposes, is called a *dividing plate*.

The above method requires a *standard*, which must be divided *originally*. This will be noticed hereafter.

Small theodolites and ordinary circular instruments must have been thus divided, previous to the invention by Ramsden of his *dividing engine*. The errors were of course large, and Mayer proposed to get rid of them by his principle of *repetition* [REPEATING CIRCLE]; but Ramsden's discovery of a machine for rapid and accurate dividing was better adapted to ordinary purposes. The general principle of Ramsden's dividing machine may perhaps be understood by the following description:—A horizontal circle of four feet diameter turns upon a vertical axis; the outer edge is ratched, or notched, by an endless screw, one revolution of which carries the circle round 10′; the pressure of the foot upon a treadle turns the screw forward, and there is a series of very ingenious contrivances which enable the divider to turn the screw through any portion of its revolution at each descent of the treadle, and which restore the position of the parts, when the foot is taken off, without allowing any return motion to the screw. The circle to be divided is fixed upon the dividing engine, and made concentric with it, and a division cut after each pressure of the foot. The Board of Longitude gave Ramsden a reward of 300*l.* for the invention of this machine, and 315*l.* for the machine itself, leaving it, during pleasure, in his possession, on condition that he would divide sextants at 6*s.* and octants at 3*s.*, for other mathematical instrument makers. Machines of a similar kind, with some alterations and improvements, have since been constructed by John Troughton, Edward Troughton, and others, and these are still employed in all instruments which are not large enough, or not sufficiently valuable, to require original dividing.

Ramsden invented a machine for dividing straight lines, in which he used a screw as his original. In the form proposed by Ramsden the machine has not been deemed of any value, since a long screw can never be made so accurate as a scale divided by bisections. Mr. Bryan Donkin has contrived a machine where a screw is indeed the scale, but where the errors of the screw are corrected by additional mechanism. We do not think that this machine has ever been figured or described, but scales have been divided, and screws cut by it of extraordinary accuracy.

Dividing engines have been constructed somewhat differently by Reichenbach and others in Germany, and by Gambey in Paris. Much of the German division is excellent, and probably superior to any English engine-dividing. It is understood to be performed by copying. A large circle having been divided originally with great care, the copy is placed upon it, and concentric with it. A microscope is fixed independently over the divided circle, the divisions are brought in succession under the wires of the micrometer, and a line is cut in the copy after each bisection. This process is much more tedious than the English engine-dividing, but it admits of the greatest accuracy when the workman is careful and expert. It is a defect in the English engine that the circle to be divided must be detached from its centre and framing, and that when reframed there is frequently a sensible excentricity, that is, the centre of the divided circle is not in the axis of rotation. This does not, however, cause any error if two or more opposite readings be used. It is a worse fault, that if the instrument be badly framed the circle may become distorted when the instrument is again put together. But when the divided limb is only a part of a circle, as in the sextant, any error of excentricity is of serious importance, and this error may be very sensible after the utmost care of the artist. [SEXTANT.] Gambey has constructed a dividing engine, by which the instrument is divided upon its own centre, but we cannot here describe the contrivance, and are not aware that it has been published.

It has not, we believe, been ascertained what average amount of error is to be feared in an English circle, engine-divided. We have not been able to learn a more important point, whether circles from the same engine are fac-similes. If they are, it would be easy to determine the error of one copy, and to apply correcting pieces to the stop of the dividing screw. This point is worth the attention of the artist, for if the engine does always give the same result, the correction would neither be troublesome nor expensive; and if it does not, nor can be made so to do, the German mode of copying must be followed where great accuracy is necessary.

In what has preceded, the existence of a standard is presumed; we will now give a brief and necessarily imperfect sketch of the art of *original* dividing. Before the invention of the telescope, almost any mode of division must have been sufficiently accurate. In a circle of three feet radius, 1′ is rather more than 0·01 inches, a quantity the half or third of which is readily seen and still more easily felt, so that the observations of Tycho and Hevelius might very well have been exact to 10″ if their greatest errors had arisen from the erroneous division of their instruments. The earliest essays in dividing which we are aware of are those of Hooke and Roemer. Hooke proposed to cut the edge of his quadrant by an endless screw, just as in Ramsden's engine, and to use the revolutions and parts of the screw as a division. This was done in Flamsteed's sector, constructed by Tompion, probably under Hooke's control, and also in his mural arc, but both the limbs were also divided into degrees by diagonal lines, &c.; and in the 'Historia Celestis,' the revolutions and parts of the screw are set down, as well as the divisions. It is found in practice that such a mode of dividing is liable to very considerable errors unless checked and corrected by independent divisions. Roemer, when he had constructed his transit-circle, directed his pupil Horrebow to describe a number of concentric circles on the limb, very near each other, and then to divide them into equal parts by *stepping* along each with a pair of compasses opened to a space of about 10′. All that he required was to have the dots round and the spaces equal; the actual value of each space was to be ascertained by finding how many were contained in the arc of 90°, *between the pole and the equator*. Horrebow informs us that only one of these series of divisions was executed which turned out exact enough to satisfy Roemer. The objection to this division is the same as to Hooke's endless screw, that there is no check upon an accumulation of small errors; still it is probable that Roemer's circle was the best divided instrument then in existence, and the idea of determining the value of the parts by observation is worthy of its author. We have no account of the way in which either Flamsteed's sector or his mural arc was was divided. All we know is that the latter instrument was divided by the "skilful hand of Abraham Sharp," then Flamsteed's assistant.

The art of dividing assumed a new form under the celebrated Graham, the father of all good clock, watch and instrument making in this country, and the worthy associate of Bradley. He pointed out the fundamental principle of original graduation, that you can divide a given line accurately into two parts, but not into three or five equal parts. The dividing tool employed by Graham was the beam-compass, a straight rod of wood or metal, on which perpendicular points of steel are fixed. Now if a line or arc is to be bisected, the points of the beam-compass are placed *nearly* at the distance of half the line, or the chord of half the arc between the dots. One point is placed in one dot, and a faint arc is struck with the other point towards the distant dot, and this operation is repeated with the second dot as a centre. The two faint arcs will either include a small space, or leave a small space between them, which can be most accurately divided with a pointer by the hand, aided by a magnifying lens. In the mural quadrant which Graham erected at Greenwich, he carried this principle into full operation. The beam-compass, which was used for drawing the divisional arc of the quadrant, was used for setting off the chord of 60°; this was bisected, and the radius being again set forward from 30°, he had the quadrant exact. The arc of 60° was divided by continual bisections into 64 (or 2^6) equal parts, and the arc of 30° in like manner into 32 (or 2^5) parts. The subdivisions were, on the same principle, into 16 parts each. This division of the quadrant into 96 parts was continued as long as quadrants remained in use, but the trouble of reducing every observation into ordinary degrees, minutes, and seconds, was a considerable increase of labour to the observer. The quadrants were generally divided to 90 as well as into 96 parts, and in Bradley's and Maskelyne's 'Greenwich Observations,' the zenith distances are recorded in both divisions, with a recommendation to trust to the 96 division in cases of discrepancy. The improvements introduced by Bird chiefly apply to the division into 90°. He made a long scale of equal parts by stepping three times with a beam compass 51·2 inches, and subdivided each of these parts by continual bisections into tenths. For further subdivision, a space of 25,856 inches was taken and divided into 256 parts by perpetual bisection; hence, as each of the new spaces was 0·101 inches, he had, with his vernier, a scale of equal parts to 0·001 of an inch. From such a scale of equal parts as this and the proper tables, all the lines of Gunter's and other scales are laid off upon a standard. In dividing the mural quadrant Bird made great use of his scale, chiefly to obtain the arc of 85° 20′, which admits of perpetual bisection, being 1024 × 5′. The chords of the several arcs were computed and beam-compasses prepared, which were adjusted by the scale to be the chords 30°, of 15°, of 10° 20′, and of 4° 40′, to the proposed radius. The scale, quadrant, and beam-compasses were then left all night to come to the same temperature, and before sunrise were examined, and readjusted if incorrect. The arc being struck, the radius marked off the chord of 60°, which was bisected with the beam-compass containing the chord of 30°, and the radius protracted from 30° gave the quadrantal arc exactly as in Graham's mode of dividing. The arc between 60 and 90 was then bisected in 75° by its proper beam-compass, the chord of 15°, and then the chord of 10° 20′ was carried forward from 75°, and the chord of 4° 40′ was carried backwards from 90°. The exact joining of these two chords in the same point proved the accuracy of the operation. The fifth beam-compass had been set to the chord of 42° 40′ and with this the arc of 85° 20′ was bisected. When this part had been subdivided, the chord of 64 subdivisions, or of 5° 20′, was taken from the divided portion and carried forward from 85° 20′, and then perpetually bisected. Bird remarks "that the points at 30°, 60°, 75°, and 90° fell in without any sensible inequality." Bird's manual skill and the great care he took to avoid errors arising from the partial expansion of the quadrant or tools during the operation gained him great and merited reputation, but we are inclined to doubt whether in engineering or theoretical accuracy of division he made any step beyond Graham. The careful division into 90° is a retrograde step.

The divisions of Graham, Bird, Ramsden, and the elder Troughton, were all performed by the beam-compass, and in a great measure by touch; magnifying lenses were indeed applied to the points of the beam-compasses, but when an erroneous point is once made, the beam-compass naturally falls into it, and there is considerable trouble in rectifying the error. A French nobleman, the Duc de Chaulnes, after perfecting the micrometer microscope for reading off the divisions of astronomical instruments [CIRCLE], first showed how it might be used in actual dividing. He did not however follow Graham's rule and proceed by perpetual bisections; hence his method was neglected, although Ramsden saw the advantage of the micrometer microscope, and used it for reading off the divisions of his circles and theodolites. In this state the art was taken up by Edward Troughton, who by a happy combination of the principle of Graham, the Duc de Chaulnes' mode of reading off, and his own ingenuity, brought the division of astronomical instruments to its present state of perfection. We will suppose that a circle is to be divided originally. After the edge of the circle is very carefully turned upon its own centre, a small circular roller, 16 revolutions of which carry it exactly round the circle, is prepared and so fitted to the circle by a radial frame joining the two centres, that on turning the frame round the roller is also turned in an opposite direction by friction between the edges of the roller and circle. The roller is divided into 16 parts, and a microscope placed over the divisions, and as each division comes under the microscope, a fine round dot is marked upon the circle, which thus receives an approximate division into 256 (or 2^8) equal parts. Troughton expected that as the roller could be carried round the circle by any number of times without over or under lapping, it would also mark out equal portions at each revolution, but he found himself mistaken, and he therefore proceeded to examine the dots optically. Two microscopes A and B are fixed above the circle, nearly in a diameter, and the dots which are to determine the divisions 0° and 180° are bisected by them. The circle is then turned half round, and dot 180° brought under A; if 0° at the same time falls exactly under B, the points are diametrically opposite, if not, the quantity and direction of the error is measured by the micrometer of B, half of which is evidently the error of dot 180°. The microscope B is then shifted and fixed over dot 90°, while A bisects 0°. By a quarter revolution of the circle 90° is brought under A, and 180° under B, and the error, if any, measured and noted. In like manner the error of dot 270° is detected, after which the microscope B is again shifted, and fixed over dot 45°, when the errors of dots 45°, 135°, 225°, and 315°, are determined. It is easily seen that this is exactly Graham's principle of perpetual bisection, only using an *optical* beam-compass instead of one without points, and *registering* the errors of the dots instead of cutting actual divisions. In this way Troughton proceeded by continual bisections to note the relative or apparent errors of the 256 dots. His next step was to compute the actual or true error of each dot, and to form a table. Suppose that in examining the 180° dot, he found that the arc from 0° to 180° was less than the arc from 180° to 360° by 20″, he would conclude that the dot 180° was 10″ behind its true place. Again, let arc from dot 0° to dot 90° exceed the arc from dot 90° to dot 180° by 30″. If 180° were right, 90° would be too forward by 15″; but as 180° is 10″ behind its true ptace, 90° will on this account alone be 5″ behind, and therefore on the whole will be 10″ too forward.* The true errors of each of the 256 dots being thus computed, Troughton returned to the roller, and by help of a small sector which revolved with it and gave him an enlarged scale, enabling him at the same time to reduce the division into 256 parts into 360° mechanically, proceeded to cut the actual divisions on the circle. This method was communicated to the Royal Society, and printed in the 'Phil. Trans. for 1809,' p. 105. The Copley medal was granted for this very valuable and original memoir. Several circles have since been divided after Troughton's method, by his successor Mr. Simms, and by Mr. Thomas Jones, and it has been thus proved that the merit of Troughton's dividing depended, as he asserted, on the excellency of his processes, and not on his manual dexterity. It is not worth while to divide a circle *originally* which is less than two feet in diameter.

There is a caution with respect to this mode of dividing which will be sufficiently obvious when pointed out,—namely, that very great care indeed must be taken that the pivots on which the circle turns shall be perfectly true and round. The circular line to be divided, and the rim on which the roller moves, are respectively drawn and turned from these pivots, and the figure of neither is a circle unless the pivots be so. The large collar of the mural circle on which the rim is turned is of steel, and several inches in diameter. It often happens that hard knots occur in the steel which ordinary tools will not touch, and it would be prudent in the artist to perform the finishing part himself with a diamond.

We should also recommend the following extension of Troughton's mode of examining his primary dots: After determining the errors of dots 0° and 180°, we should leave the microscopes A and B undisturbed, and fix two new microscopes, C and D, at 90° and 270°. Then, having adjusted C and D in 90° and 270°, and having ascertained their errors, as has been already described, the circle should be turned round till 0° and 180° are bisected by B and A, when 90° is under D and 270° under C. The errors are then to be again determined exactly as before. Now, if the circle turn round a mathematical point, the two results must, of course, be identical; but if not, it may happen that the observations will give two errors for dot 90° and two for dot 270°, which should, however, have the same difference. The final error, or that which the artist should adopt, for each dot, is the *mean* of the two determinations, which will give the position of a line at right angles to the diameter from 0° to 180°, and the nearest possible to the variable centre. It is also clear when this discrepancy is found that the centre has not been properly turned. By extending the above process to the dots which bisect the quadrants,—that is, shifting the microscopes C and D to 45° and 225°,—and trying the dots, as in Troughton's method, and also after a half-revolution, a series of bisecting diameters may be found which will cut the diameters already determined at angles of 45°, and pass as near the variable centre as may be. This process should be continued one or two steps more, and then Troughton's method may be considered sufficient for the rest. If the above system of examination should appear too troublesome, it would be at least advisable, when Troughton's subdivision has been carried to 16 or 32 parts, that the table of true errors should be checked by opposite readings. This is easily done by bringing each dot in its turn under microscope A, and reading off the apparent error of the opposite dot by microscope B. As the true error of the dot under A is known from the table of errors, this, + the apparent error as shown by B, should = the true error of the dot under B, which is also known from the table of errors. Any sensible discrepancy in these two values will show a faultiness in the centre. Again, if the artist have, as he ought to have, a convenient pier and a sufficiency of micrometer microscopes, he may ascertain the errors of his four or eight primary dots, by placing four or eight equidistant microscopes round his circle, and reading off at each quarter or one eighth of a revolution. It would be prudent to repeat this several times and on several days, selecting the times when the temperature had been and promised to be steady. This principle might be carried on farther in examining a graduated circle by changing the number of microscopes. Indeed, if the centre were very irregular, and therefore the curve traced out by its revolution, a better division into equal parts might be got after a preliminary division by *stepping* than by Troughton's method unaltered. As the + and − signs used in forming the tables of apparent and true errors may cause a little confusion, it is usual to cut a few slight divisions, which may easily be rubbed out, and thus to *test* the accuracy of the table of errors before commencing the actual division.

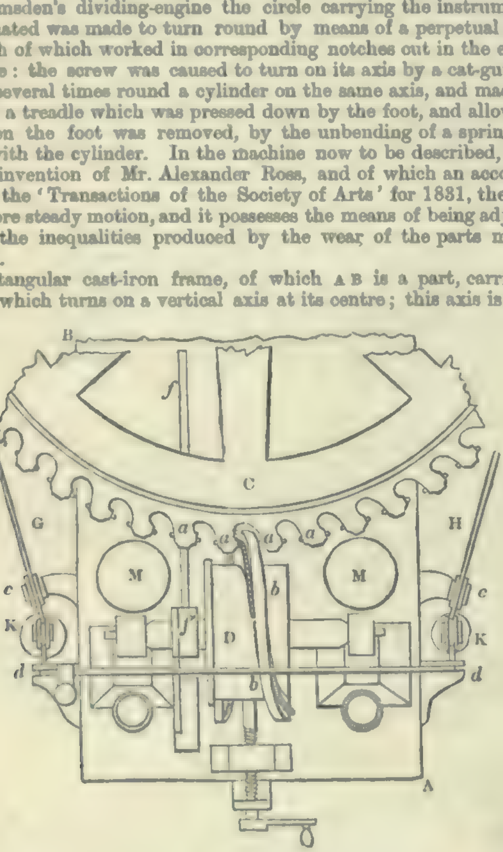
---

* Let ι and ι' be the errors of any two dots, a and b, + when too forward, and − when behind their true place, and the distance to the bisecting dot c be from $a = m$ and from $b = m + k$: then the apparent error of c is $-\frac{k}{2}$; for it should be at a distance $m + \frac{k}{2}$ from a. But the dot a is wrong ι, and the dot b is wrong ι'; therefore there is a further correction of $\frac{\iota+\iota'}{2}$, and the whole error of c is (attention being paid to the signs) $\frac{\iota+\iota'}{2}\ \frac{k}{2}$; from which expression the mode of forming the table of real errors is very evident, care being taken not to confound the signs, and also to pass from the arcs to the half arcs in succession.

It is easy to see how Bird's method of dividing a scale may be pursued, adopting microscopes instead of the beam-compass. The examination of such a scale is completely exemplified in Mr. Baily's memoir referred to in the sequel.

In Ramsden's dividing-engine the circle carrying the instrument to be graduated was made to turn round by means of a perpetual screw, the teeth of which worked in corresponding notches cut in the edge of the circle: the screw was caused to turn on its axis by a cat-gut band passing several times round a cylinder on the same axis, and made fast below to a treadle which was pressed down by the foot, and allowed to rise, when the foot was removed, by the unbending of a spring connected with the cylinder. In the machine now to be described, which was the invention of Mr. Alexander Ross, and of which an account is given in the 'Transactions of the Society of Arts' for 1831, the circle has a more steady motion, and it possesses the means of being adjusted, so that the inequalities produced by the wear of the parts may be obviated.

A rectangular cast-iron frame, of which A B is a part, carries the circle C, which turns on a vertical axis at its centre; this axis is in the form of two frustums of cones, and its lower extremity rests in a cup which is at one end of a lever; at the other end is applied a counterpoise which, causing a pressure upwards on the axis, diminishes the pressure of the circle on the frame which supports it. Round the circumference of the circle are 48 projections, *a*, *a*, *a*, &c.; and at one end (A) of the rectangular frame, a sliding apparatus carries a cylinder D, which turns on a horizontal axis, and has on its convex surface a spiral projection (*b b*) like a rectangular thread of a screw; this enters between the projections *a*, *a*, &c., and the distance between the two turns of the spiral is rather greater than the breadth of one of those projections.



On the rim of the circle C, and under the projections *a a*, &c., is a groove in which enters an endless cat-gut band, G H; on each side of the frame, at the end A of the latter, this band passes over a fixed pulley, *c*, and under a moveable pulley, from which is suspended a weight, K: it then passes through a notch at *d*, and above the frame, in the direction *d d*.

Four pillars, of which M M are two, rising from the rectangular frame A B, support a stage which carries the tool for cutting the divisions on the instrument to be graduated: the apparatus by which the cutting-tool is connected with the stage is formed with joints so as to allow the tool to be moved up or down, or in the direction of a radius of the circle C, but neither to the right nor left of that radius; and there is a contrivance for determining the length of the lines of division.

By moving one end of a lever at the opposite extremity of the frame A B, a bar, *f f′*, which is attached at one end to that lever, gives motion to a catch, or click, so as to cause a ratchet-wheel to turn on its axis, and thus give the requisite movement to the cutting-tool: the other extremity, *f*, of the bar, by turning a lever on a horizontal axle containing within it the axle of the cylinder D, allows a catch, or click, to turn a ratchet-wheel on the latter axle, and, with it, the cylinder itself; and thus a side of the spiral projection *b b* is removed a little way from its position when in contact with one side of a projection *a*. Moving then the first-mentioned lever back again, a spring, which had previously pressed against the cat-gut band on the circumference of C, is drawn off; and thus one of the weights, K, by drawing down the band and pulley above it, gives a small movement to the circle C, and consequently brings the side of a projection *a* again in contact with the side of the spiral. According to the place at which the bar *f f′* is applied to the lever on the axle of D, the catch may pass over any required number of the teeth of the ratchet-wheel; and thus the circle C may be turned through any angle consistently with the values of the divisions intended to be cut.

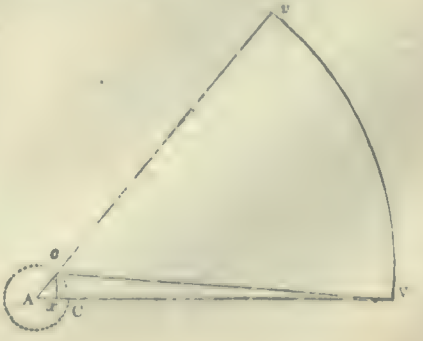
Through each of the projections *a a*, &c., passes a steel screw, whose ends appear in the above cut: and through the spiral thread *b b* pass a number of steel screws, whose ends also appear. The right-hand extremity (in the diagram) of each of the former screws is ground quite flat and perpendicular to the length of the screw; while the left-hand extremities of the screws in *b b* are turned in the form of hemispheres; and, after every movement of the circle C and of the spiral *b b*, the machine is held in a state of rest by the abutment of the hemispherical end of one screw against the flat end of the other.

The original divisions on the circle C are made on silver studs let into its surface; and the screws passing through *a*, *a*, &c., are so adjusted, by means of their capstan heads, that if the end of a screw in *b b* is in contact with the screw in any one of the projections *a*, one complete revolution of the spiral *b b* may bring the end of the screw in the next projection *a* in contact with the same screw in the spiral. The corresponding movement in the circle is equivalent to the interval between two of the original graduations; and the movement is verified by the primitive divisions coming successively to a wire in a microscope.

It may be useful, before we give a list of references for the history and practice of graduation, to point out the effect of excentricity in engine-divided circles, which is almost always mistaken for bad dividing by unskilful persons. If the centre of the divided circle is not concentric with the axis of rotation (we here suppose the circle to revolve, and the verniers or microscopes to be fixed), it is clear that the centre of the divisions will describe a very small circle about the axis. Now, suppose we set out from the position when the centre of the divisions is in a line with and between the axis and the reading apparatus. On turning the circle a little round, it will be seen that the angle through which the instrument *really* moves is less than the angle read off at that vernier or microscope; and on drawing the figure it will be seen that the angle read off is the exterior angle of a triangle of which the true angle is the interior and opposite; and also that the error or the difference between these two angles is the other interior angle of the triangle, the measuring arc of which to the same radius is, as to sense, equal to a perpendicular from the centre of divisions on the primary line.* Hence the error caused in any vernier by *excentricity* is an arc equal to the distance between the two centres × sine of the angle from the position we have set out from. From this consideration it will be evident to one who knows the nature of trigonometrical lines, that two, three, or any number of equidistant readings will cure excentricity, as the + errors must always equal the − errors. Now, if the possessor of a circular instrument having

---

* Let A be the axis of rotation, C c the circle described by the centre of the divided circle V v V the place of the reading. In the position first mentioned in the text, *c* coincides with C, and *v* with V. When the instrument has been moved round the angle V A *v*, the angle *read off* is V *v* or V *c v*, and the error is the angle A V *c*, which is $\frac{cx}{cV} = \frac{Ac}{AV} \times \sin VAc$.



two or more equidistant readings wishes to examine the divisions, he may get rid of the effect of excentricity thus :—Take the mean of the readings at every 10°, 20°, or 30°, and subtract each reading from the mean. It will be seen whether the differences thus obtained can be represented under the form of a constant quantity $+x'' \times \sin.\ \theta$, where θ is reckoned from some definite point. If they can, there is no error of division, and the residual quantities, when the above equation has been satisfied in the best practicable manner, will give some insight into the quality of the divisions. The error which arises from the original circular form changing to an ellipse by a fall or other injury is of the form $y'' \times \sin.\ 2\phi$, where ϕ is the angle from some definite point of the divisions. Hence two readings at right angles, or three equidistant readings, will compensate each other; so that three or more equidistant readings will destroy the effect of both excentricity and ellipticity. In like manner the effect of any error which obeys a law may be investigated, when the law is known, and also the number of microscopes. Hitherto four or six microscopes seem to have made every circle a well-divided one.

The mode of reading the parts of larger divisions has been partly explained in the description of the microscope, article CIRCLE [ASTRONOMICAL], and will be finished under the head VERNIER.

The principal sources of information on this subject are :—'The Method of Dividing Astronomical Instruments,' by Mr. John Bird. London, 1767. 'Nouvelle Méthode pour diviser les Instruments de Mathématique et d'Astronomie,' par M. le Duc de Chaulnes, 1768. 'Description of an Engine for dividing Mathematical Instruments,' by Mr. J. Ramsden. London, 1777. Troughton's Memoir, 'Phil. Trans., 1809, p. 105. Graduation, 'Edinburgh Cyclopædia.' This very valuable article is by Troughton. 'On the Errors of the Cape Mural Circle,' by Messrs. Sheepshanks and Airy, 'Memoirs Royal Astronomical Society,' vol. v., p. 325. 'On the Cape Mural Circle,' by Professor Henderson, 'Memoirs Royal Astronomical Society,' vol. viii., p. 141. 'Description of the Mural Circle of the Armagh Observatory,' by Dr. Robinson, 'Memoirs Royal Astronomical Society,' vol. ix., p. 17. 'Report on the Standard Scale of the Royal Astronomical Society,' by Mr. F. Baily, 'Memoirs Royal Astronomical Society,' vol. ix., p. 35. In the Introductions to the 'Cambridge Observations' for 1833-4-5, and the Introduction to the 'Greenwich Observations' for 1836, will be found several instances of the way of examining the divisions of astronomical circles. See also article CIRCLE, and the references there given.

GRAFTING is an operation by which a portion of one individual of the vegetable kingdom is applied to another which is within certain limits of physiological affinity, so as to form a vital union, and consequently produce a reciprocal growth. Thus a species bearing small and austere fruit may be cut down, and the remaining part grafted with a scion from a tree of which the fruit is large and delicious; and being nourished, but not changed in any essential character, this scion will form a tree, ultimately producing fruit similar in every respect, all other circumstances being the same, to that of the tree from which it was taken. The shoots of any particular variety may be cut into many hundred pieces, if sufficiently numerous, and, by grafting, each of them can be made to possess all the properties of an individual tree in the course of one season. In the case of cultivated fruits, as well as in many varieties of ornamental plants, multiplication by seeds is precarious; and with regard to *hybrids* it is impracticable, at least no assurance can be had of a reproduction of the same variety; on the contrary, a disposition is generally manifested to return to the natural wild state of the species. Grafting is in some instances the only means, and in many it is the most eligible, of preventing this. By it the peculiar richness of the fruit or the delicate tint of the flower which we especially prefer and admire can be perpetuated in an almost infinite series of individuals, each being the result of augmentation of the comparatively small original portion—this portion being placed in favourable circumstances for receiving an abundant supply of new and proper matter, on which it exercises its organising powers, and effects a perfect assimilation, which causes a similar development of leaves, flowers, and fruit. Again, this newly-formed augmentation being every way similar to that from which it was derived, it will continue to exercise the same functions with regard to such new matter as comes within the extending scope of its organising powers, the progress only becoming arrested by such causes as naturally limit the growth of the parent tree. Propagation by cuttings, it is true, will equally continue the variety unchanged; but that process in numerous instances is slow: in others success is not attainable to any considerable extent.

From what has been stated, the great importance and utility of the process about to be explained will be sufficiently evident.

The limits within which grafting may be effected extend to species and varieties of the same genus, or at all events are confined within the same natural order. Pears may be grafted not only on other pears, but also on the quince (which is very frequently done), and on the medlar, white thorn, or mountain ash. Peaches are budded either on the almond, or more frequently on the plum, their own roots not being suited to the cold soil of this country. In these cases, although the leaves and fruit of the peach and the plum, the pear and the mountain ash, have a very different appearance, yet botanists have determined that the stock and the scion belong to the same natural order.

As one species is often grafted on another of a different genus, it is necessary therefore to state the reason why such is in many cases more proper than on species of the same genus; and this leads to the consideration of the effects generally produced by the stock upon the graft. When the stock is of slower growth than the graft, as in the case of the white thorn and quince stocks and the pear, the consequence is a partial obstruction of the flow of the sap, which checks the over-luxuriance of the pear-tree, and its natural disposition to produce only wood for a number of years of its youth; the juices, rendered less abundant, become more inspissated, and fruitfulness is induced at an earlier age. This condition may be even carried too far; for the common quince increases so slowly in diameter compared with the generality of pears, that its vessels become inadequate for a sufficient supply of nourishment. The French, aware of this, employ the Portugal quince as a stock for their pears, because its wood increases more in accordance with that of the latter. On the same principle (that is to say, a less copious supply of nourishment) trees are rendered more dwarf than they naturally are, and hence are better adapted for small spaces. On the contrary, a weak species will have a tendency to grow stronger if grafted on one naturally more vigorous. These are modifications induced by the stock on the graft extremely necessary to be known and attended to: for instance, apple-trees on crab-stocks, if injudiciously planted in a small garden, will soon overgrow their limits; whereas on the French paradise stock, the dwarfest of any, they are easily managed within a very small space; besides, the roots of the latter are very fibrous, and run near the surface, which renders them eligible for planting over a bad subsoil. Many species and varieties both of fruits and ornamental plants, natives of a warmer soil, are advantageously grafted on their hardier congeners, such as the peach and apricot on the plum, Chinese tender roses on the wild roses of our hedges, and many ornamental species of Cratægus on the C. Oxyacantha.

The methods of grafting are of great variety. M. Thouin ('Monographie des Greffes') has enumerated 43 modes of grafting, 39 of inarching, and 28 of budding. Many of these are however more curious than useful; and not worth being detailed. It will be better to explain the principle on which all modes of successful practice must depend, either as regards grafting, budding, or inarching.

It is well known that the bud of a plant has the power of becoming a distinct individual, if separated from the parent and placed in circumstances sufficiently favourable for its future development. But no development can take place unless the portion abstracted from any plant contain either a bud, or the perfectly formed rudiments of one. Hence the portion intended to be propagated must contain a bud or buds. The diametrical increase of exogenous plants proceeds outwardly, in consequence of the formation of new layers of alburnum, interwoven into the peculiar texture of the tree by extensions of the medullary rays. The alburnum is interposed between the inner bark and the heartwood, with both of which it is in vital or organised union. The greater part of the heartwood of a tree may be bored out, and, though made a hollow cylinder, it will still continue to increase. The outer bark may be removed, and a new one will gradually be formed; but, if the alburnum be entirely destroyed, death will be the consequence.

It appears therefore that buds with some portion of alburnum are the parts essentially necessary for propagation; for although the heartwood and bark be organised, yet they are but passively so, and have not the power of extending organisation to new matter when they are deprived of the media of buds and alburnum. Keeping therefore the importance of the latter in view, the best mode of operation is that whereby the greatest possible extent of the alburnum of the stock and graft is brought into exact contact, without making too extensive a wound. If the sections of alburnum can be made to coincide in every point, the result of the operation will be the most perfect that can be obtained.

The modes of grafting most generally practised are whip, cleft, saddle, and crown grafting. Of these *whip-grafting* is by far the commonest, and is performed as follows :—the stock is cut over, sloping, above a smooth and straight part. The end of the scion is cut sloping and thin towards the lower end. Then on the same side of the stock as that of the lowest part of the slope made in cutting off its top, a slice is cut clean off, in length equal to that of the cut part of the scion, and in breadth so as to expose as much of the wood of the stock as will equal that seen in the slanting section of the scion. Both sections should be smooth and plain, and as regards the alburnum, they should be the exact counterparts of each other; or, if this cannot generally be the case, the coincidence should be as exact as can be on one side at least. A thin wedge-shaped tongue is made very near the upper part of the slope in the scion, and a corresponding nick in the stock to receive it. The top part of the scion is shortened to two or at most three buds, and fitted to the stock, to which it is tied with a strip of pliable matting; and the parts so united are then covered with grafting-clay, or some other composition, which remains till the graft has pushed, or as long as there is no danger of the matting, used as a ligature, cutting or galling the parts when they begin to grow and to have an enlarged circumference. After the first loosening it is often advisable to apply slightly a fresh bandage immediately; and in some cases a little clay or composition may be put round, should the union appear too tender to endure exposure to the vicissitudes of the weather.

Cleft-grafting is performed by splitting the stock diametrically across the top, which should be cut horizontally, and then nicely inserting in one side a scion cut like a wedge. This mode is objectionable, because the deposition of young wood takes place for the most part in a projection exterior to the circumference of a circle having for its centre the axis of the stock; the top of the latter is consequently left long uncovered and becomes unsound from the wood being split to admit the graft.

Saddle-grafting is the reverse of the preceding, inasmuch as the stock, instead of the scion, is formed like a wedge; and the end of the scion made to fit over it, like a saddle. It is preferable to cleft-grafting, particularly where the stocks are small, or nearly of the same size as the scion; but when the stocks are large, it is by no means to be recommended.

Crown-grafting is performed on large limbs with thick bark, or on large stems; in either case these are cut off at right angles; the bark is raised by thrusting in a tapering flattened piece of smooth hard wood, or ivory, between the wood and bark; this being withdrawn, the end of the scion, properly thinned as if for whip-grafting, but without the tongue, is inserted. Three or four scions may with propriety be thus inserted in the same branch or stem. This method is objectionable for the following reasons: the section of the scion is plane; the part of the stock to which it is appled is circular; consequently, these surfaces can only come into partial contact. Again the abrasion must be considerably larger than the space covered by the scion, particularly if the bark of the stock be rigid. If we compare this state with the principle laid down in the preceding part of this article, the result will be, what ample experience has proved to be the case, that even on large trees whip-grafting is preferable. In fact, the cavity on each side of the scion in crown-grafting must be filled with something; either air, which is injurious, or if the tree be vigorous, a deluge of sap will flow to it; and it often happens that this, technically speaking, drowns the graft.

Cuttings intended for scions should be taken from the trees before the movement of the sap commences in spring, and put in moderately moist earth or sand, and out of the sun's rays. If the stocks be cut down at the same time it will be so much the better; any large limbs of trees which it may be found necessary to graft should by all means be cut in before vegetation becomes active, otherwise extravasation takes place and canker is in consequence induced.

Grafting Clay may be made from any smooth clay, or adhesive clayey yellow loam, or brick-earth, mixed with one-third, or, according to some, one-half of cow-dung, free from litter, excepting that of hay, and if it contain none of the latter, some fine hay must be beaten up with the mixture; the hay answers the same purpose as hair in plaster. A mixture of clay and horse-dung is preferred by some. The fact is, that any composition will answer that will exclude the air, retain some degree of moisture, and at the same time prove not injurious to the barks of the stock and scion which it surrounds.

Grafting Wax, a compound of pitch, rosin, bees'-wax, hogs'-lard, and turpentine, has had a great reputation as a means of fixing the scion to the stock, but it is liable to two serious objections. In the first place it does not adhere and exclude air unless both stock and scion are perfectly dry when it is used; secondly, the winds in March, the general period of grafting, are excessively drying, and were it not for the moisture absorbed from the clay the scion would frequently be shrivelled, and dried up before it had time to vegetate; but resinous substances do not permit of any similar absorption of beneficial moisture.

Inarching is a species of grafting, the success of which depends on the principles above explained. It is sometimes called grafting by approach, because in performing the operation the branches or stems of two contiguously growing plants are made to approach and unite; and this union is effected on the same principles as that of whip-grafting. Corresponding slices are taken off, a small slit being made upwards in the part that is to form the head, and another correspondingly downwards in the stock; being joined, the wounded parts are tied together, and covered with moss or grafting-clay. When properly united, that which is to form the top is by degrees severed from its parent root, and thus transferred it ultimately becomes the sole ascending stem of the one to which it was made to unite.

It is generally believed that although the stock and scion are organically united by the operation of grafting, yet no other effect follows the operation than what may arise from the slowness or quickness with which the stock allows the sap to rise upwards into the scion; and it is generally believed that the scion exercises no influence whatever upon the stock. It is however perfectly certain that a bud of a variegated jasmine, made to grow upon one branch of a large tree of a plain jasmine, will gradually give the variegated appearance to the plain stock. This was long since asserted, then denied, but has been since proved to be true by new experiments.

GRAIN (*granum*, a seed), an old measure of weight, the smallest of those in use. It is of about the weight of a seed of wheat corn, and must therefore be considered rather as a theoretical aliquot part of a larger weight, than as itself a proper standard of weight. We shall therefore refer to Weights and Measures, Avoirdupois, Troy, &c., for further information, stating in the present article all that refers to this particular measure. The word has not only designated a weight, but a coin. Ducange mentions an ancient Neapolitan piece of money called a grain, and the *grano* is still used in reckoning in Naples, Sicily, and Malta, though there are not now any coins so called.

By a statute passed in the reign of Edward III. (1266), it was enacted that 32 grains of wheat taken out of the middle of the ear, and well dried, should weigh a pennyweight, of which 20 should make an ounce, of which 12 should make a pound. Consequently the pound (troy), of this period consisted of 7680 grains, whereas that afterwards in use had only 5760. The reason was, that it became usual to divide the same pennyweight into 24 instead of 32 grains. This must have occasioned an alteration either in the value of the pound or of the grain. The former has been sometimes stated, but we believe the latter. The value of the average grain of wheat is stated by Paucton at ·86 of the grain of the *poids de marc*, that is, at about seven-tenths of our modern English grain. But if 32 grains of real weight were made to weigh 24 grains so called, the grain of wheat would be ·75 of the weight called a grain; which comes near the preceding. It is certainly possible that the grain of French wheat may differ from that of the English; and it is also known that the weight of grain varies considerably in different harvests and under different modes of culture. This latter circumstance rather affords a presumption that it was the wheat which varied: it is not at all unlikely that improved agriculture gave wheat of which 24 grains were equivalent to 32 of the more ancient harvests. According to Dr. Bernard's measurement, the grain of barley is ⅔, or ·67 of the troy grain.

However this may be, the grain must have lost much of its importance by the introduction of the avoirdupois pound, of which it is not a constituent aliquot part. The ancient avoirdupois pound is variously stated at from 7009 grains to less than 7000, at which latter number it is now fixed by law.

The grain has varied considerably in different countries: Dr. Bernard mentions the Rabbinical grain, which was two-thirds of the English grain; the money grain of Venice and Paris (that of the poids de marc above noticed), which he places at ·8334 of the English grain; and the physicians' grain of the Greeks, Arabs, and Venetians, which was ·9166 of the English grain.

The weight of one grain is obtained, for practical purposes, without difficulty, by weighing a thin plate of metal of uniform thickness, and cutting out by measurement such a proportion of the whole plate as should give one grain. But a much better plan is to draw a given weight of ductile metal into very thin wire, and to cut from the wire that length which is the same proportion of the whole length as a grain is of the whole weight. In this way pieces of wire are obtained for chemical purposes which weigh only the thousandth part of a grain; and even less weights might be obtained, if it were necessary.

GRAMMAR. [Language.]

GRAND JURY. [Jury.]

GRAND SERJEANTY, one of the ancient English tenures. The tenant, instead of rendering to the king pure military service, was bound to perform in person some special honorary service to the sovereign himself, as to carry his banner, or to be his butler, champion, or other officer at his coronation. It was in most other respects like knight service. Tenure by grand serjeanty still exists so far as relates to merely honorary services, but the burdensome incidents were taken away by the stat. 12 Car. II. c. 24.

GRANDEE. *Grande de España* is the name of the highest rank in the Spanish nobility. The grandees were originally the descendants of the great feudatories of the crown, but since the time of Don Carlos I. (Charles V. of Germany), who unceremoniously excluded them from the national assembly of the Cortes, it became the practice of the Spanish kings to raise new men to the rank of grandees, with the double object of rewarding their friends and at the same time breaking down the pride and influence of an order which was to them an object of jealousy. This occasioned a distinction between the old and new grandees, which was marked by the old ones addressing each other always in the second person singular, "thou," and by being addressed "excellenza," without distinction of age or official station; whilst they addressed on all occasions those of a recent creation by the title of "your excellency," which belongs to all Spanish grandees, with studied punctiliousness. The old grandees had the privilege of being covered in presence of the monarch; and now, the elevation to the rank of grandee is announced by the monarch desiring him to be covered. Few of the old families are now extant in a direct line.

All the grandees of Spain, and also the Titulos de Castilla, or marquises with a Castilian title, had a right to sit in the old Cortes whenever the king pleased to convoke them, and they did so sit in the Cortes assembled, in 1789, as the representatives of the estamento, or order of the nobility. The collective body of the grandees is called La Grandeza, but they have no political privileges under the present constitution, as there is no hereditary house of legislature at present in Spain. The titulos, or lower nobility, are excessively numerous, and are addressed as su señoria, abbreviated in common speech to ussia.

GRANT (Concessio), in law, is technically and strictly a conveyance in writing of incorporeal hereditaments, or of such interests in or arising out of land whereof no livery or actual tradition can be made.

All corporeal hereditaments, as lands and houses, of which actual delivery can be made, are said to lie in livery; but advowsons, commons, rents, reversions, &c., which from their nature cannot so be transferred, are said to lie in grant. This distinction has been removed by modern legislation, and a grant may now be made of every species of property. At common law, as at present, a writing was necessary to support a grant; the writing being the evidence of such transfer of property, as livery of seisin was in the case of a feoffment. Until the statute 4 Ann. c. 16, sc. 9, the ceremony of attornment was necessary in such grants of interests in reversion or remainder as are grantable; that is, the tenant in possession consented to the grant of the seignory, by which consent he became tenant to the new lord.

Attornment was a consequence of the feudal law, and until the ceremony was rendered unnecessary by the statute cited, and by another (11 George II., c. 19), the doctrine relating to it was one of the most confused and difficult branches of the law.

GRANULATION. [WOUND.]

GRAPE SHOT is an assemblage, in the form of a cylindrical column, of nine balls resting on a circular plate, the size of the bore of the gun, through which passes a pin serving as an axis. The balls are contained in a strong canvas bag, and are bound together or quilted on the exterior of the latter by a cord disposed about the column in the manner of a net; they then have something of the appearance of a bunch of grapes. From the rusting of the iron shot the canvas becomes soon destroyed, hence another description of grape shot, sometimes called tier shot, has been introduced; the balls are retained round the iron pin by a series of flat iron plates, screwed down parallel to the lower plate, and between every two of which is a layer of balls.

The dimensions of a column, or assemblage of balls, and the sizes of the balls in the column, vary from 4 lbs. to 8 oz. with the nature of the ordnance from which they are to be discharged; according to the present method the grape shot are adapted to 6, 9, 12, 18, 24, and 32-pounder guns, but their weights are rather greater than those of the usual shot which correspond to each nature of gun.

A fire of grape shot is on service frequently directed against an enemy's troops when advancing in close order to an attack, and on board ship at close quarters: 600 yards is considered the limit of the effective range of grape.

GRAPE SUGAR. [SUGAR.]

GRAPE VINE. [VINE.]

GRAPHIC ACID. [GRAPHOTE.]

GRAPHITE. *Plumbago. Black Lead.* The natural sources of this variety of carbon, and the uses to which it is applied, have already been described. See GRAPHITE, in NAT. HIST. DIV.

The artificial formation of graphite occurs in several manufacturing processes. For example, when cast-iron is melted in contact with charcoal, a quantity of the latter is dissolved, and on the cooling of the mass, crystallises out in characteristic six-sided plates; closely resembling that variety of graphite now largely imported from Ceylon. Crystalline graphite is also deposited in the retorts used in the manufacture of coal-gas. Amorphous graphite—similar to that obtained from the Borrowdale mines in Cumberland and from Germany—is deposited on one of the carbon terminals of the electric-light apparatus during the passage of the current.

For most of the useful purposes to which it is applied, graphite requires to be freed from the impurities with which, in the native state, it is nearly always contaminated. To this end, a process, discovered by Professor Brodie, has recently been made the subject of a patent. Its details are as follows:—One pound of powdered graphite is mixed with four pounds of concentrated sulphuric acid, and one ounce of powdered chlorate of potash is then added. The mixture is heated until chlorous fumes cease to be evolved, the residue is then thrown into water, washed, dried, and ignited. The ignited substance is washed in water, on which it floats, while the impurities fall to the bottom. Lastly, it is dried. By this process the graphite may be obtained in a state of chemical purity.

The phenomenon that ensues during the ignition of the substance just described is very peculiar, much resembling that which takes place on the application of heat to the bichromate of ammonia. Gases are given off in the interior of the little grains or plates, the whole swells up to very many times its original bulk, and is reduced to the most minute state of division.

According to Professor Brodie's researches, the composition of the body that results from the oxidation of graphite as above detailed, is not constant. It contains the elements of sulphuric acid combined with oxygen, with hydrogen, and with a large per centage of carbon. By repeating the oxidising process, however, five or six times, the whole of the graphite is converted into a light-yellow, transparent, crystalline substance, to which Professor Brodie has given the name *Graphic Acid.* It contains:—

Carbon	61·11
Hydrogen	1·85
Oxygen	37·04
	100·00

Corresponding with the formula $C_{22}H_4O_{10}$. Graphic acid is very slightly soluble in water, combines with the alkalies to form crystalline salts, and is reduced by deoxidising agents to a body resembling graphite.

GRASS LAND may be divided into water-meadows, upland pastures, and artificial grasses. The first are treated of under IRRIGATION: the nature and management of the two last we shall here briefly describe. Upland pastures are portions of land on which the natural grasses grow spontaneously, varying in quantity and quality with the soil and situation. The plants which form the natural sward are not confined to the family of the Gramineæ, but many other plants, chiefly with perennial roots, form part of the herbage. In the richest soils the variety is exceedingly great. When a sod is taken up, and all the plants on it are examined, the species will be found more numerous than we should have believed possible;[*] and in the same ground the plants will vary in different years, so as to induce one to conclude that, like most other herbaceous plants, the grasses degenerate when they have grown for a long time on the same spot, and that a kind of rotation is established by nature. It is chiefly in those pastures where the grasses are allowed to grow till they form their seed that this is observable; for when they are closely fed, and not allowed to shoot out a seed-stem, they are less subject to degenerate and disappear. This may be a reason why experienced dairymen are so unwilling to allow their best pastures to be mown for hay. They pretend that the feed is deteriorated in the next year, and that inferior grasses are introduced which injure the quality of their butter and cheese. Close feeding is always considered as the most advantageous, both to the cattle and the proprietor.

The only way in which a pasture can be profitable is by feeding stock; and its value is in the exact proportion to the number of sheep or cattle which can be fed upon it in a season. Extensive pastures are often measured only by their capacity in this respect. Thus, we speak of downs for 1000 sheep; and in Switzerland and other mountainous countries they talk of a mountain of 40, 60, or 100 cows, without any mention of extent in acres.

When a pasture is naturally rich, the only care required is to stock it judiciously, to move the cattle frequently from one spot to another (for which purpose inclosures well fenced are highly advantageous), and to eradicate certain plants which are useless or noxious, such as docks and thistles, furze, broom, briars and thorns, which, not being touched by the cattle as long as they have better food, would increase and overrun the ground, and take up a space which would be more profitably occupied by good herbage. The dung of the cattle also, when left in heaps as it is dropped, kills the grass and introduces coarse and less palatable plants. This must be carefully beat about and spread, or carried together in heaps to make composts with earth, to manure the poorer meadows or the arable land. All that is required in rich pastures in which cows and oxen are fed, and which are properly stocked, is to prevent the increase of the coarser and less nutritive plants. Weeding is as important in grass as in arable land; and if it is neglected, the consequence will soon be observed by the inferior quality of the feed. The urine of the cattle is the manure which chiefly keeps up the fertility of grass land; and although in hot and dry weather it frequently burns up the grass where it falls, when it is diluted by showers the improved appearance of the surface shows that its effect has not been detrimental. To enrich poor meadows there is no manure so effective as diluted urine, or the drainings of stables and dung-hills.

When pastures are poor, and the herbage is of a bad quality, the cause is to be sought for in the soil. A poor arid soil is not fitted for grass, nor one which is too wet from the abundance of springs and the want of outlet for the water. These defects can only be remedied by expensive improvements. A soil which is too dry may be improved by cultivation and judicious manuring; but for this purpose it must be broken up and treated for some time as arable land: and it may be a question whether or not the expense of improving the soil will be repaid by the superior quality of the pasture when it is again laid down to grass. In general the poor light soils, if they are worth cultivation, answer better as arable land, especially where the turnip husbandry is well understood. The low wet clay soils may be converted into good pastures by draining them well; and the improvement thus produced is so great, that judicious draining in such soils is the most profitable investment of capital.

When old meadows have been neglected, or too often mown, without being recruited by manure or irrigation, they are often overrun with moss or rushes, and produce nothing but a coarse sour grass. In that case, besides draining it if required, the land must be broken up and undergo a regular course of tillage, until the whole of the old sward is destroyed, and a better collection of grasses covers its surface. If this be done judiciously, the pasture will not only be greatly improved in the quality, but also in the quantity of the grass. There is a natural prejudice against the breaking up of old grass land. This has arisen from the improper manner in which it is frequently effected. The sward when rotten is a powerful manure, and produces great crops of corn. These tempt the farmer to repeat the sowing of corn on newly broken up lands. The fertility is reduced rapidly; and when grass seeds are sown after several crops of corn, the soil has been deprived of a great portion of the humus and vegetable matter which is essential to the growth of rich grass. The proper method of treating grass land, broken up to improve it, is to take no more corn crops than will pay the expense of breaking up, carting earth, lime, or other substances upon it, to improve the soil, and to lay it down to grass again as soon as the old sward is fully destroyed.

---

[*] In a sod of grass taken from Selborne Common, the following grasses were found: *Plantago lanceolata, Agrostis capillaris, Avena flavescens, Dactylis glomerata, Festuca duriuscula, Poa annua, Cynosurus cristatus, Trifolium repens, Crepis tectorum, Achilea millefolium, Galium verum, Hypochæris radicata, Hieracium pilosella, Thymus serpyllum.* (Curtis 'On Grasses.')

If the soil is fit for turnips, no better crop can be sown to prepare for the grass seeds, which should be sown without a corn crop, except where the sun is powerful, and the seed is sown late in spring: but autumn is by far the best season for sowing grass seeds for permanent pasture. Turnips of an early kind may be sown in May, and fed off with sheep in August or September; and the ground being only very slightly ploughed, or rather scarified, and harrowed fine, the seeds may be sown and rolled in. The species of grasses sown must depend on the nature of the soil; but it is impossible to be too choice in the selection. That mixture of chaff and the half-ripe seeds of weeds, commonly called hay seeds, which is collected from the stable lofts, should be carefully rejected, and none but seeds ripened and collected on purpose should be sown. The *Trifolium repens* (white clover), the *Trifolium medium* (cow grass), *Medicago lupinula* (trefoil), *Lolium perenne* (rye grass), the poas and festucas, are the best kinds of grasses. A very easy way of obtaining good seed is to keep a piece of good meadow shut up from the cattle early in spring, carefully weeding out any coarse grasses, and letting the best arrive at full maturity; then mow and dry the crop, and thresh it out upon a cloth. This will give the best mixture of seeds; but some of the earliest will have been shed, and these should be collected separately, or purchased from the seedsmen. Before winter, the ground will already be covered with a fine green, if the seed has been plentiful. The quantity per acre of the mixed seeds should not be less than 30 or 40 pounds to insure a close pile the next year. If the soil is not naturally rich, liquid manure, or urine diluted with water, should be carried to the field in a water-cart, and the young grass watered with it. This will so invigorate the plants that they will strike and tiller abundantly.

The following are lists of seed proper for different soils, taken from Mr. Lawson's 'Agriculturist's Manual,' pp. 203, 4, 5, 6.

"In preparing grass seeds for sowing in mixture, it has been found that a reference to weight is more correct in practice than to measure; and for the sake of comparison, the tables, giving the average weight of a bushel of each kind of seed, are here inserted.

WEIGHT OF THE SEEDS OF GRASSES AND OTHER PLANTS, PER IMPERIAL BUSHEL.

	lbs.		lbs.
Agrostis stolonifera	13	Festuca tenuifolia	13
„ vulgaris	13	„ pratensis	12½
Aira flexuosa	6½	„ rubra	10
Alopecurus geniculatus	6	„ sylvatica	10½
„ pratensis	5½	Glyceria fluitans	14½
Arrhenatherum arenacerum	7	Poa glauca	7½
Anthoxanthum odoratum	6	„ nemoralis	18¾
Avena flavescens	5	„ pratensis	13¼
Briza media	10¼	„ trivialis	15¼
Cynosurus cristatus	26	Holcus lanatus	7
Dactylis glomerata	11½	Lolium perenne, the varieties vary from	18 to 30
Elymus arenarius	9½	„ italicum	16½
Festuca duriuscula	9¾	Phalaris arundinacea	48
„ elatior	20	Phelum pratense	44
„ heterophylla	12¼	Poa annua	14
„ loliacea	15	„ aquatica	18½
„ ovina	13½		

CLOVERS AND OTHER PLANTS.

	lbs.		lbs.
Achillea Millefolium	26¼	Trifolium pratense	62
Hedysarum Onobrychis	26	„ cow-grass	62
Lotus major	64	„ procumbens	64
Medicago lupulina	63¾	„ repens	65
Plantago lanceolata	51¼	Vicia sepum	65
Poterium Sanguisorba	24½	„ cracca	66
Trifolium minus	64½	„ sylvatica	64

"In sowing down grass lands *without a crop*, the benefit in hay or pasture is sooner acquired, without the soil being in any degree exhausted by a corn crop. In most cases, however, a greater quantity of seed is necessary, than where the young grass enjoys the protection and shelter afforded by a cereal crop. These advantages may in a great measure be gained in sowing down grass lands without a crop, and with a considerable saving of grass seeds, by sowing along with the mixture, a bushel of rye or of winter barley per acre, in autumn sowing, for shelter in winter; and a bushel of barley per acre for protecting the young plants from the scorching drought of summer, when sown in spring; observing that the barley or rye shall be eaten or cut down while in a green state.

"Although *Lolium italicum*, when sown in too great a proportion, from its strong habit of growth is apt to choke or weaken the clovers, yet by substituting 5 lb. of it for 8 lb. *Lolium perenne* in the above table, the produce will be materially improved.

QUANTITY OF GRASS SEED PER IMPERIAL ACRE.

I. *For Alternate Husbandry.*

	Light and Medium Soil.			Heavy Soils.		
	1 Year's Hay.	1 Year's Hay and 1 year's Pasture.	1 Year's Hay and 2 years' Pasture.	1 Year's Hay.	1 Year's Hay and 1 year's Pasture.	1 Year's Hay and 2 years' Pasture.
	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.

Trifolium pratense *perenne*	3	4	3	4	3	4
„ repens	4	5	4	5	4	5
Also barley, or rye, as in the last table.	28	34	33	38½	30	45

"The foregoing table (ii.—1.) is drawn out with a view to the strictest economy as regards the original outlay: yet by introducing 4 lb. *Lolium italicum* for 5 lb. *Lolium perenne*, the bulk of pasture will be increased, and the quality improved; and where the value of the seeds of *Lolium italicum* does not exceed three or four times those of *Lolium perenne*, a more profitable return upon the whole will be yielded by its introduction.

"The next table (ii.—2.) contains a greater proportion of the more rare and valuable sorts of seeds, although these will add considerably to the first expense, yet the improved produce will annually give a greater return; and to the mixture in both tables may be introduced with advantage, on dry and elevated sheep pastures, 2 lb. to 4 lb. of *Festuca ovina*; on dry light lands, ½ lb. *Achillea Millefolium*; on dry calcareous soils, 6 lb. to 10 lb. *Onobrychis sativus*; in some cases 1 lb. to 2 lb. of *Cichorium Intybus*; and 2 lb. *Apium petroselinum* on lands where sheep are subject to liver-rot; and in all cases when a crop of hay is intended to be taken the first year, 2 lb. *Lolium perenne*, 1 lb. *Lolium italicum*, and 2 lb. *Trifolium pratense* should be added."

In a recent volume of the English Agricultural Society's 'Journal,' some valuable information was given by Mr. Thompson, its editor, and Mr. Dixon, a Cheshire land agent and agriculturist, on the management and improvement of grass lands, of which we give the following account:—

Mr. Thompson's paper is more especially devoted to the consideration of the best method of treating newly laid down grass, in order to success in the production of a good permanent pasture. He states that, after long experience and repeated failures in the attempt to establish a pasture by folding sheep year after year on the young grass, he "became satisfied that to graze sheep on young seeds intended for permanent pasture was a mistake, and that in all probability it had been the cause of several previous failures. Up to that time," says Mr. Thompson, "I had never succeeded to my own satisfaction in laying down land to grass; but since making a rule rigidly to exclude sheep for some years from newly-laid grass during the season of active growth, I have never had a failure, though I have twice had occasion, for local reasons, to lay down fields of which the soil was strong clay. The method which I have found to answer best has been to sow a liberal allowance of the hay-seeds of the district, with a sprinkling of cow-grass and white clover; to sow them with a crop of wheat (one of the short-strawed varieties); to mow the first year, and as soon as the hay is removed, to give a good dressing of farm-yard manure, and then for some years pasture it with cattle, beginning for the first year or two with young stock, until the turf is close and strong enough to bear the treading of heavy cattle. If farm-yard manure is not to be had, 3 cwt. of best Peruvian guano per acre will prove a tolerable substitute, though by no means equal to the former. For some years a newly-laid pasture will, unless the land be of *very* superior quality, require assistance from time to time to keep it in an improving state: an occasional dressing of farm-yard manure is, of course, the best; but as this is rarely obtainable in sufficient quantity, it must be eked out by other means."

The following are among the more striking of the experiences of various top-dressings for pasture land recorded by Mr. Dixon:—

1. *On Boning alone.*—"A great improvement by bone manure was effected by Captain De Hollenworth, of Hollenworth Hall, Cheshire, between the years 1840 and 1843. In those three years about 1500*l.* was expended on bones, principally boiled, and about 4*l.* in value was used to the acre. Boiled bones at that time cost 4*l.* per ton; raw broken bones, 7*l.* per ton. The land where the manure was used is nearly 600 feet above the sea; old turf; the climate does not mature corn well: character of the soil varies, some peaty, on aluminous shale or stone; other parts a lightish gray soil, on aluminous slaty stone. It was on the latter description of soil that the bones effected the greatest change. The grass had sometimes been eaten off, and sometimes mown for hay. The quality of the herbage was totally changed within the first two years after boning. Some of the meadow land which had been let at 30*s.* per acre was readily raised to 3*l.*, and still made more money for the tenant when turned either to the feeding and breeding of sheep or the feeding of cattle. In the year 1841 Mr. Williamson, a tenant farmer residing at Huxley, near Tarporling, expended 374*l.* in bones, principally boiled. Mr. Williamson's farm is 50 miles south-west of Captain De Hollenworth's farm, and is 60 feet above the sea. The whole of the bones were applied to grass land, at a cost of 2*l.* 10*s.* per acre. Mr. Williamson's pasture land has a peculiarly close-textured soil and subsoil, approaching nearly to the lias clay, though brown-red in colour, and effervesces violently when tested with spirits of salts. Previous to boning, the herbage on these pastures was of the poorest kind imaginable, there being few if any plants except the small carex; in the second summer after boning the carex had disappeared, and the pasture had become long and thick-set with white clover, cow-grass or marl clover, and trefoil. The dairy stock had also been increased from 40 to 52 cows: the 40 cows had been at times almost starved; the 52 cows had abundance, and more than they could feed down, and sheep were purchased for the excess keep."

2. *On Boning with Drainage.*—"In the year 1838 I inspected a farm 28 miles west of Captain De Hollenworth's. The altitude of this was about 80 feet above the sea. Up to August in that year 250*l.* had been expended in boiled bones (cost 4*l.* per ton); the quantity applied to the acre was about 16 cwt., the soil and subsoil being much the same as on Mr. Williamson's farm; the herbage growing on it of the same kind, but apparently more scanty. Several small fields had not been dressed with the manure, nor had any stock been in these fields during the summer up to the month named. So little, however, was the herbage, that I computed that not more than 20 stones of hay could be obtained from an acre. In 1839 I again inspected this farm, and the pastures showed considerable improvement. The dairy stock on the farm the preceding year consisted of four cows, which had been increased to eight. It is proper to mention here, that the land in question had been in grass for a long series of years, its wetness and natural cohesiveness having been a bar to any attempt at converting it to tillage. The extent of the farm in question is 98 acres. In 1842 the dairy stock on this farm was 24 cows, and in the autumn of that year 80 sheep were put on the land to consume the superabundant grass on the pastures. In November, 1843, I again inspected this farm. The weather had been wet for some weeks, and I was sorry to see much good herbage on the land almost lost for want of the surface-water being properly carried off. Within the past two years I have been three times over this farm; it is still in a bad state from want of efficient drainage, and the bones seem to have lost much of their former effect."

3. *On Liming.*—"In the year 1845 a gentleman purchased several hundred acres of land in small farms, all lying in a district of country about 600 feet above the level of the sea, neither the land nor its occupants being in a position to help one another. But the gentleman wishing to see the land of his early days wear a more pleasing appearance, even at great cost, the thing was to be attempted. It was almost to an acre old grass land, as corn at that elevation will not often reach maturity. I was engaged to direct the re-modelling of the fields, and the manuring of nearly all the property. Most of the soil lay on poor clay or shale, and lime was used to a great extent. Rather extensive draining was done on the clay land; and the material thrown out of the drains being of a soft and very cohesive character, we did not return it into the drains. It was mixed with lime; and our object being to destroy or reduce the nature of the clay, we put clay and lime together in about equal bulk: the lime nearly burnt the clay; to do that about 14 days were required. The compost was then turned over altogether in a powdery state. In due course it was applied to the land, and in a few weeks there was ample evidence that the practice was correct. The compost acted sooner than lime alone would have done; it has been *equally*, or, I might say, to some extent *more* effective. About 1000 tons of lime have been used on these small farms, at the rate of 8 or 9 tons to the acre, and a great improvement brought about. The lime costs here 12*s.* per ton. It was brought 30 miles by water, and 2½ miles by carts. In one year after the lime had been applied, 10*s.* to 15*s.* per acre advance in rent was readily obtained. Bones have been used here to a limited extent, but, unless applied in double the quantity sufficient for most lands in low altitudes, the change is not satisfactory."

In some soils which are not congenial to grass the seed does not take so well as in others; and there is a great difficulty in producing a good sward. In this case recourse may be had to planting, or, as some call it, inoculating grass. This is done by taking pieces of sward from an old meadow, and spreading them over the surface of the land to be laid down, after it has been ploughed and prepared in the same manner as it would be to receive the seed. The turf of the old meadow is taken up with a peculiar instrument in strips two inches wide and these strips are cut across so as to form little square pieces, which are spread over the ground, leaving about five or six inches of interval between every two pieces. The heavy roller presses them into the ground. These tufts soon spread and fill up all the intervals with a complete old sward. This is a very effectual and certain method of producing a permanent pasture. Some attention is required to prevent weeds in the intervals between the tufts at first: by going over the field with a narrow hoe, all weeds may be easily kept down; and the roots and tillers of the grass soon fill up the vacant spaces.

The fertility produced by grass which is fed by cattle and sheep has given rise to the practice of converting arable land to pasture for a certain time in order to recruit its strength. The old notion was that the land had *rest*, which by a confusion of ideas was associated with the rest of the labourers and the horses. Ploughing was called working the land; and some men talked of working out the heart of the land by ploughing. That the ploughing of land does not diminish the productive power of all soils that are fit for cultivation, will be readily allowed. The sea sand no doubt, where a few bents have taken root, would not be improved by being stirred; neither would very light soils under a burning sun: but in our moist climate there is seldom any danger of over-ploughing. The land, by being in grass, has much vegetable matter added to it from the fibres of the roots which die and decay, as well as from the other parts of the grass, which draw nourishment from the atmosphere and impart it to the roots. Thus in time an accumulation of vegetable soil is formed; and when the land is ploughed the rotting of the sward greatly increases it. Every species of plant thrives well in this improved soil; and the vigour of the growth is ascribed to the recruiting effects of rest, by a fancied analogy with the animal muscle, which is invigorated by occasional inaction.

But setting aside theory, it is well known that land which has been some years in grass is improved in fertility. The convertible system of husbandry takes advantage of this fact; and all its art consists in reproducing a good pasture without loss of time, after having reaped the benefit of the fertility imparted to the land during three or four years when it was in grass. Good pasture is very profitable; so are good crops: by making the one subservient to the other, the farmer who adopts the convertible system is enabled to pay higher rents, and still have a better profit than those who adhere to a simple rotation of annual crops.

When an arable field is sown with the seeds of grasses and other plants which give herbage for cattle, it is called an artificial meadow, and the various plants which are raised are all called artificial grasses, although many of them have no botanical title to the name of grass, such as clover, saintfoin, lucern, and many others, which produce the best pastures and the finest hay.

In laying down a field to grass for a very few years the mode of proceeding is somewhat different from that which is recommended for producing a permanent pasture. Clover in this case is always a principal plant, both the red and the white; these with annual or perennial rye grass are sown with a crop of corn in spring, and begin to show themselves before harvest. The grasses are often mown the first year after they are sown, on account of the abundance and value of the red clover, but the best farmers recommend the depasturing them with sheep, to strengthen the roots and increase the bulk. Various circumstances, such as a greater demand for clover hay, or for fat cattle, may make mowing or feeding most profitable; but when there is not a decided advantage in making hay, feeding should always be preferred. At all events the great object of the farmer should be to have his land in good heart and tilth, and free from weeds, when the grass is sown. If his grass is good, he is certain of good crops after it with little trouble or manure.

The seeds usually sown on an acre, when the land is laid down to grass, are as follows:—Red clover, 12 lb.; white, 6 lb.; trefoil, 4lb.; rib grass, 2 lb.; and 2 pecks of Pacey's rye grass. Sometimes cockfoot grass (*Dactylis glomerata*) and cow grass (*Trifolium medium*) are added. This is for a field intended to remain four or five years in grass.

The introduction of artificial meadows, in districts where the soil seemed not well adapted for pasture, has greatly increased the number of cattle and sheep reared and fattened, and has caused greater attention to be paid to the means of improving the breeds of both. Thus a double advantage has arisen: the public is benefited by an increased supply, and the farmer is rewarded by an additional source of profit.

In the neighbourhood of large towns there are many meadows, which, without being irrigated, are mown every year, and only fed between hay harvest and the next spring. These require frequent manuring to keep them in heart, and with this assistance they produce great crops of hay every year. The management of this grass land is well understood in Middlesex. Sometimes the meadows are manured with stable dung which has been laid in a heap for some time, and been turned over to rot it equally. This is put on soon after the hay is cut, and the rains of July wash the dung into the ground; but if a very dry and hot summer follows, little benefit is produced by the dung, which is dried up, and most of the juices evaporated. A better method is to make a compost with earth and dung, and, where it can be easily obtained, with chalk, or the old mortar of buildings pulled down. The best earth is that which contains most vegetable matter; and as many of these meadows are on a stiff clay soil, which requires to be kept dry by open drains and water furrows, the soil dug out of these and carted to a corner of the meadow makes an excellent foundation for the compost. It is sometimes useful to plough furrows at intervals to take off the superfluous surface-water in winter; the earth thus raised by the plough is excellent to mix in the compost; having been turned over with dung, sweepings of streets, or any other manure, so as to form a uniform mass, it is spread over the land in winter; and in spring a bush-harrow is drawn over the meadow, and it is rolled with a heavy roller. All this compost is soon washed into the ground, and invigorates the roots of the grass. It is better to put on a slight coating of this compost every year than to give a greater portion of manure every three or four years, as is the practice of some farmers. When grass land is let to a tenant, it requires some attention, and particular conditions in the lease, to prevent the meadows being deteriorated by continual mowing without sufficient manuring, which might be the case near the expiration of the lease. It is very common to insist, by a clause, on a cart-load of stable dung being bought for every load of hay which is made and not consumed on the premises. Sometimes the tenant is bound to feed the land in alternate years; but if horses or heavy cattle should be taken in, especially in spring and autumn, they may do more harm by their treading, when the ground is soft, than would have been done by taking off a crop of hay. When the proprietor of meadows resides near them, he often finds it most profitable to keep them in hand, and sell the crop when it is fit to be mown. In that case he must be careful to manure them sufficiently, or his profits will soon diminish rapidly. The grazing of cattle has generally been a more profitable occupation than simply tilling the land. The capital required is considerable, but the current expenses are not great. The grazier is not subject to such total failures as the farmer of arable land is in his crops. With a little experience and prudence, he can always reckon on a certain return. An acre of good grazing land, worth 40s. rent, is supposed to produce 200 lb. of meat in the year. If this is worth 6*d.* a pound, the gross produce is 5*l.* per acre. The expenses will not exceed 10*s.* per acre, so that here is a net profit of 2*l.* 10s. per acre with little or no risk; few arable farms will average this net profit. By uniting the raising of corn and the grazing of cattle and sheep, the greatest profit is probably obtained, and this is the great argument in favour of the convertible system of husbandry.

The value of pasture land, and of some of the sown grasses, especially the Italian rye-grass, under irrigation and under the application of sewage-manure, will be considered hereafter. [Irrigation.]

GRAVE. [Accent.]

GRAVER. [Engraving.]

GRAVITATION. Section I.—*On the Rules for calculating Attraction, or the Law of Gravitation.*

(1.) The principle upon which the motions of the earth, moon, and planets are calculated is this: Every particle of matter *attracts* every other particle. That is, if there were a single body alone, and at rest, then, if a second body were brought near it, the first body would immediately begin to move towards the second body. Just in the same manner, if a needle is at rest on a table, and if a magnet is brought near it, the needle immediately begins to move towards the magnet, and we say that the magnet attracts the needle. But magnetic attraction belongs only to certain bodies: whereas the attraction of which we speak here belongs to all bodies of every kind: metals, earths, fluids, and even the air and gases are equally subject to its influence.

(2.) The most remarkable experiments which prove that bodies attract each other are a set of experiments made at the end of the last century by Mr. Cavendish. Small leaden balls were supported on the ends of a rod which was suspended at the middle by a slender wire; and when large leaden balls were brought near to them, it was found that the wire was immediately twisted by the motion of the balls. But the results of this experiment are striking, principally because they are unusual; the ordinary force of gravity serves quite as well to prove the existence of some such power. For when we consider that the earth is round, and that, on all parts of it, bodies, as soon as they are at liberty, fall in directions perpendicular to its surface, (and therefore fall in opposite directions at the places which are diametrically opposite,) we are compelled to allow that there is a force such as we call attraction, either directed to the centre of the earth, or produced by a great number of small forces, directed to all the different particles composing the earth. The peculiar value of Cavendish's experiment consists in showing that there is a small force directed to every different particle of the earth.

(3.) But it is necessary to state distinctly the rules by which this attraction is regulated, and by which it may be calculated; or (as it is technically called) *the law of gravitation*. Before we can do this, we must determine which of the effects of attraction we choose to take as its measure. For there are two distinct effects: one is the *pressure* which it produces upon any obstacle that keeps the body at rest; the other is the *space through which it draws the body in a certain time*, if the obstacle is removed and the body set at liberty. Thus, to take the ordinary force of gravity as an instance: we might measure it by the pressure which is produced on the hand by a lump of lead held in the hand; or we might measure it by the number of inches through which the lump of lead would fall in a second of time after the hand is opened (as the pressure and fall are both occasioned by gravity). But there is this difference between the two measures: if we adopted the first, since a great lump of lead weighs more than a small one, we should find a different measure by the use of every different piece of lead; whereas, if we adopt the second, since it is well established by careful and accurate experiments that large and small lumps of lead, stones, and even feathers, fall through the same number of inches in a second of time, (when the resistance of the air, &c., is removed,) we shall get the same measure for gravity, whatever body we suppose subject to its influence. The consistence and simplicity of the measure thus obtained incline us to adopt it in every other case; and thus we shall say, *Attraction is measured by the space through which it draws a body in one second of time after the body is set at liberty.*

(4.) Whenever we speak, therefore, of calculating attraction, it must be understood to mean calculating the number of inches, or feet, through which the attraction draws a body in one second of time.

(5.) Now the first rule is this: "The attraction of one body upon another body does not depend on the mass of the body which is attracted, but is the same whatever be the mass of the body so attracted, if the distances are the same."

(6.) Thus Jupiter attracts the sun, and Jupiter attracts the earth also; but though the sun's mass is three hundred thousand times as great as the earth's, yet the attraction of Jupiter on the sun is exactly equal to his attraction on the earth, when the sun and the earth are equally distant from Jupiter. In other words, (the attraction being measured in conformity with the definition above,) when the sun and the earth are at equal distances from Jupiter, the attraction of Jupiter draws the sun through as many inches, or parts of an inch, in on second of time as it draws the earth in the same time.

(7.) The second rule is this: "Attraction is proportional to the mass of the body which attracts, if the distances of different attracting bodies be the same."

(8.) Thus, suppose that the sun and Jupiter are at equal distances from Saturn; the sun is about a thousand times as big as Jupiter; then whatever be the number of inches through which Jupiter draws Saturn in one second of time, the sun draws Saturn in the same time through a thousand times that number of inches.

(9.) The third rule is this: "If the same attracting body act upon several bodies at different distances, the attractions are inversely proportional to the square of the distances from the attracting body.

(10.) Thus the earth attracts the sun, and the earth also attracts the moon; but the sun is four hundred times as far off as the moon, and therefore, the earth's attraction on the sun is only $\frac{1}{160000}$th part of its attraction on the moon; or, as the earth's attraction draws the moon through about $\frac{1}{20}$th of an inch in one second of time, the earth's attraction draws the sun through $\frac{1}{3200000}$th of an inch in one second of time. In like manner, supposing Saturn ten times as far from the sun as the earth is, the sun's attraction upon Saturn is only one hundredth part of his attraction on the earth.

(11.) The same rule holds in comparing the attractions which one body exerts upon another, when, from moving in different paths, and with different degrees of swiftness, their distance is altered. Thus Mars, in the spring of 1833, was twice as far from the earth as in the autumn of 1832; therefore, in the spring of 1833, the earth's attraction on Mars was only one-fourth of its attraction on Mars in the autumn of 1832. Jupiter is three times as near to Saturn, when they are on the same side of the sun as when they are on opposite sides; therefore, Jupiter's attraction on Saturn, and Saturn's attraction on Jupiter, are nine times greater when they are on the same side of the sun than when they are on opposite sides.

(12.) The reader may ask, How is all this known to be true? The best answer is, perhaps, the following: We find that the force which the earth exerts upon the moon bears the same proportion to gravity on the earth's surface which it ought to bear in conformity with the rule just given. For the motions of the planets, calculations are made, which are founded upon these laws, and which will enable us to predict their places with considerable accuracy, if the laws are true, but which would be much in error if the laws were false. The accuracy of astronomical observations is carried to a degree that can scarcely be imagined; and by means of these we can every day compare the observed place of a planet with the place which was calculated beforehand, according to the law of gravitation. It is found that they agree so nearly as to leave no doubt of the truth of the law. The motion of Jupiter, for instance, is so perfectly calculated, that astronomers have computed ten years beforehand the time at which it will pass the meridian of different places, and we find the predicted time correct within half a second of time.

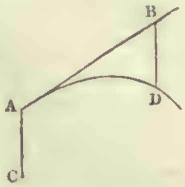
SECTION II.—*On the Effect of Attraction upon a Body which is in motion, and on the Orbital Revolutions of Planets and Satellites.*

(13.) We have spoken of the simplest effects of attraction, namely, the production of pressure, if the matter on which the attraction acts is supported (as when a stone is held in the hand), and the production of motion if the matter is set at liberty (as when a stone is dropped from the hand). And it will easily be understood, that when a body is projected, or thrown, in the same direction in which the force draws it (as when a stone is thrown downwards), it will move with a greater velocity than either of these causes separately would have given it; and if thrown in the direction opposite to that in which the force draws it (as when a stone is thrown upwards), its motion will become slower and slower, and will, at last, be turned into a motion in the opposite direction. We have yet to consider a case much more important for astronomy than either of these: Suppose that a body is projected in a direction *transverse to*, or *crossing*, the direction in which the force draws it, how will it move?

(14.) The simplest instance of this motion that we can imagine is the motion of a stone when it is thrown from the hand in a horizontal direction, or in a direction nearly horizontal. We all know that the stone soon falls to the ground; and if we observe its motion with the least attention, we see that it does not move in a straight line. It begins to move in the direction in which it is thrown; but this direction is speedily changed; it continues to change gradually and constantly, and the stone strikes the ground, moving at that time in a direction much inclined to the original direction. The most powerful effort that we can make, even when we use artificial means (as in producing the motion of a bomb or a cannon-ball), is not sufficient to prevent the body from falling at last. This experiment therefore will not enable us immediately to judge what will become of a body (as a planet) which is put in motion at a great distance from another body, which attracts it (as the sun); but it will assist us much in judging generally what is the nature of motion when a body is projected in a direction transverse to the direction in which the force acts on it.

(15.) It appears then that the general nature of the motion is this: the body describes a curved path, of which the first part has the same direction as the line in which it is projected. The circumstances of the motion of the stone may be calculated with the utmost accuracy from the following rule, called the second law of motion (the accuracy of which has been established by many simple experiments, and many inferences from complicated motion). If A, *fig.* 1, is the point from which the stone was thrown, and A B the direction in which it was thrown; and if we wish to know where the stone will be at the end of any particular time (suppose, for instance, three seconds), and if the velocity with which it is thrown would, in three seconds, have carried it to B, supposing gravity not to have acted on it; and if gravity would have made it fall from A to C, supposing it to have been merely dropped from the hand; then, at the end of three seconds, the stone really will be at the point D, which is determined by drawing B D parallel and equal to A C; and it will have reached it by a curved path A D, of which different points can be determined in the same way for different instants of time.

Fig. 1.

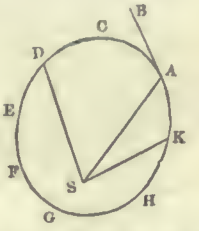


(16.) The calculation of the stone's course is easy, because, during the whole motion of the stone, gravity is acting upon it with the same force and in the same direction. The circumstances of the motion of a body attracted by a planet, or by the sun (where the force, as we have before mentioned, is inversely proportional to the square of the distance, and therefore varies as the distance alters, and is not the same, either in its amount or in its direction, at the point D as it is at the point C), cannot be computed by the same simple method. But the same method will apply, provided we restrict the intervals for which we make the calculations to times so short, that the alterations in the amount of the force, and in its direction, during each of those times, will be very small. Thus, in the motion of the earth, as affected by the attraction of the sun, if we used the process that we have described, to find where the earth will be at the end of a month from the present time, the place that we should find would be very far wrong; if we calculated for the end of a week, since the direction of the force (always directed to the sun) and its magnitude (always proportional inversely to the square of the distance from the sun) would have been less altered, the circumstances would have been more similar to those of the motion of the stone, and the error in the place that we should find would be much less than before; if we calculated by this rule for the end of a day, the error would be so small as to be perceptible only in the nicest observations; and if we calculated for the end of a minute, the error would be perfectly insensible.

(17.) Now a method of calculation has been invented, which amounts to the same as making this computation for every successive small portion of time, with the correct value of the attractive force and the correct direction of force at every particular portion of time, and finding thus the place where the body will be at the end of any time that we may please to fix on, without the smallest error. The rules to which this leads are simple: but the demonstration of the rules requires the artifices of advanced science. We cannot here attempt to give any steps of this demonstration; but our plan requires us to give the results.

(18.) It is demonstrated that if a body (a planet for instance) is by some force projected from A, *fig.* 2, in the direction A B, and if the attraction of the sun, situated at S, begins immediately to act on it, and continues to act on it according to the law that we have mentioned (that is, being inversely proportional to the square of its distance from S, and always directed to S); and if no other force whatever but this attraction acts upon the body; then the body will move in one of the following curves—a circle, an ellipse, a parabola, or a hyperbola.

Fig. 2.



In every case the curve will, at the point A, have the same direction as the line A B: or (to use the language of mathematicians), A B will be a tangent to the curve at A.

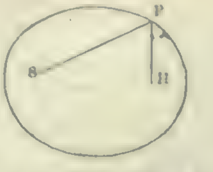
The curve cannot be a circle unless the line A B is perpendicular to S A, and, moreover, unless the velocity with which the planet is projected is neither greater nor less than one particular velocity determined by the length of S A and the mass of the body S. If it differs little from this particular velocity (either greater or less), the body will move in an ellipse; but if it is much greater, the body will move in a parabola or a hyperbola.

If A B is oblique to S A, and the velocity of projection is small, the body will move in an ellipse; but if the velocity is great, it may move in a parabola or hyperbola, but not in a circle.

If the body describe a circle, the sun is the centre of the circle.

If the body describe an ellipse, the sun is not the centre of the ellipse, but one focus. (The method of describing an ellipse is to fix two pins in a board, as at S and H, *fig.* 3; to fasten a thread S P H to them, and to keep this thread stretched by the point of a pencil, as at P; the pencil will trace out an ellipse, and the places of the pins S and H will be the two focuses.)

Fig. 3.



If the body describe a parabola or hyperbola, the sun is in the focus.

(19.) The planets describe ellipses which are very little flattened, and differ very little from circles. Three or four comets describe very long ellipses; and nearly all the others that have been observed are found to move in curves which cannot be distinguished from parabolas. There is reason to think that two or three comets which have been observed move in hyperbolas. But as we do not propose, in this treatise, to enter into a discussion on the motions of comets, we shall confine ourselves to the consideration of motion in an ellipse.

(20.) Everything that has been said respecting the motion of a planet, or body of any kind, round the sun, in consequence of the sun's attraction according to the law of gravitation, applies equally well to the motion of a satellite about a planet, since the planet attracts with a force following the same law (though smaller) as the attraction of the sun. Thus the moon describes an ellipse round the earth, the earth being the focus of the ellipse; Jupiter's satellites describe each an ellipse about Jupiter, and Jupiter is in one focus of each of those ellipses; the same is true of the satellites of Saturn and Uranus.

(21.) In stating the suppositions on which the calculations of orbits are made, we have spoken of a force of attraction, and a force by which a planet is projected. But the reader must observe that the nature of these forces is wholly different. The force of attraction is one which acts constantly and steadily without a moment's intermission (as we know that gravity to the earth is always acting): the force by which the body is projected is one which we suppose to be necessary at some past time to account for the planet's motion, but which acts no more. The planets *are in motion*, and it is of no consequence to our inquiry how they received this motion, but it is convenient, for the purposes of calculation, to suppose that, at some time, they received an impulse of the same kind as that which a stone receives when thrown from the hand; and this is the whole meaning of the term "projectile force."

(22.) From the same considerations it will appear that, if in any future investigations we should wish to ascertain what is the orbit described by a planet after it leaves a certain point where the velocity and direction of its motion are known, we may suppose the planet to be projected from that point with that velocity and in that direction. For it is unimportant by what means the planet acquires its velocity, provided it has such a velocity there.

(23.) We shall now allude to one of the points which, upon a cursory view, has always appeared one of the greatest difficulties in the theory of elliptic revolution; but which, when duly considered, will be found to be one of the most simple and natural consequences of the law of gravitation.

(24.) The force of attraction, we have said, is inversely proportional to the square of the distance, and is therefore greatest when the distance is least. It would seem then, at first sight, that when a planet has approached most nearly to the sun, as the sun's attraction is then greater than at any other time, the planet must inevitably fall to the sun. But we assert that the planet begins then to recede from the sun, and that it attains at length as great a distance as before, and goes on continually retracing the same orbit. How is this receding from the sun to be accounted for?

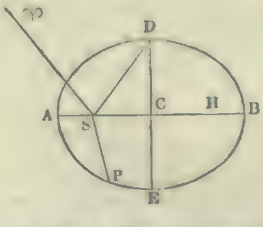
(25.) The explanation depends on the increase of velocity as the planet approaches to the point where its distance from the sun is least, and on the considerations by which we determine the form of the curve which a certain attracting force will cause a planet to describe. In explaining the motion of a stone thrown from the hand, to which the motion of a planet for a very small time is exactly similar, we have seen that the deflection of the stone from the straight line in which it began to move is exactly equal to the space through which gravity could have made it fall in the same time from rest, whatever were the velocity with which it was thrown. Consequently, when the stone is thrown with very great velocity, it will have gone a great distance before it is much deflected from the straight line, and therefore its path will be very little curved; a fact familiar to the experience of every one. The same thing holds with regard to the motion of a planet; and thus the curvature of any part of the orbit which a planet describes will not depend simply upon the force of the sun's attraction, but will also depend on the velocity with which the planet is moving. The greater is the velocity of the planet at any point of its orbit, the less will the orbit be curved at that part. Now if we refer to *fig.* 2, we shall see that, supposing the planet to have passed the point C with so small a velocity that the attraction of the sun bends its path very much, and causes it immediately to begin to approach towards the sun: the sun's attraction will necessarily increase its velocity as it moves through D, E, and F. For the sun's attractive force on the planet, when the planet is at D, is acting in the direction D S, and it is plain that (on account of the small inclination of D E to D S) the force pulling in the direction D S helps the planet along in its path D E, and thereby increases its velocity. Just as when a ball rolls down a sloping bank, the force of gravity (whose direction is not much inclined to the bank) helps the ball down the bank, and thereby increases its velocity. In this manner, the velocity of the planet will be continually increasing as the planet passes through D, E, and F; and though the sun's attractive force (on account of the planet's nearness) is very much increased, and tends, therefore, to make the orbit more curved, yet the velocity is so much increased that, on that account, the orbit is not more curved than before. Upon making the calculation more accurately, it is found that the planet, after leaving C, approaches to the sun more and more rapidly for about a quarter of its time of revolution; then for about a quarter of its time of revolution the velocity of its approach is constantly diminishing: and at half the periodic time after leaving C, the planet is no longer approaching to the sun; and its velocity is so great, and the curvature of the orbit in consequence so small (being, in fact, exactly the same as at C), that it begins to recede. After this it recedes from the sun by exactly the same degrees by which it before approached it.

(26.) The same sort of reasoning will show why, when the planet reaches its greatest distance, where the sun's attraction is least, it does not altogether fly off. As the planet passes along H, K, A, the sun's attraction (which is always directed to the sun) retards the planet in its orbit, just as the force of gravity retards a ball which is bowled up a hill; and when it has reached C, its velocity is extremely small; and, therefore, though the sun's attraction at C is small, yet the deflection which it produces in the planet's motion is, (on account of the planet's slowness there) sufficient to make its path very much curved, and the planet approaches the sun, and goes over the same orbit as before.

(27.) The following terms will occur perpetually in the rest of this article, and it is therefore desirable to explain them now.

Let S and H, *fig.* 4, be the focuses of the ellipse A E B D; draw the line A B through S and H; take C the middle point between S and H, and draw D C E perpendicular to A C B. Let S be that focus which is the place of the sun, (if we are speaking of a planet's orbit,) or the place of the planet, (if we are speaking of a satellite's orbit).

Fig. 4.



Then A B is called the *major axis* of the ellipse.

C is the *centre*.

A C or C B is the *semi-major axis*. This is equal in length to S D; it is sometimes called the *mean distance*, because it is half-way between A S (which is the planet's smallest distance from S) and B S (which is the planet's greatest distance from S).

D E is the *minor axis*, and D C or C E the *semi-minor axis*.

A is called the *perihelion* (if we are speaking of a planet's orbit); the *perigee* (if we are speaking of the orbit described by our moon about the earth); the *perijove* (if we are speaking of the orbit described by one of Jupiter's satellites round Jupiter); or the *perisaturnium* (if we are speaking of the orbit described by one of Saturn's satellites about Saturn.)

B, in the orbit of a planet, is called the *aphelion*; in the moon's orbit it is called the *apogee*; in the orbit of one of Jupiter's satellites, we shall call it the *apojove*.

A and B are both called *apses*; and the line A B, or the major axis, is sometimes called the *line of apses*.

S C is sometimes called the *linear excentricity*: but it is more usual to speak only of the proportion which S C bears to A C, and this proportion, expressed by a number, is called the *excentricity*. Thus, if S C were one-third of A C, we should say, that the excentricity of the orbit was $\frac{1}{3}$, or 0·3333.

If S ♈ is drawn towards a certain point in the heavens, called the *first point of Aries*, then the angle ♈ S A is called the *longitude of perihelion* (or of perigee, or of perijove, &c.).

If P is the place of the planet in its orbit at any particular time, then the angle ♈ S P is its *longitude* at that time, and the angle A S P is its *true anomaly*. (The longitude of the planet is, therefore, equal to the sum of the longitude of the perihelion, and the true anomaly of the planet.) The line S P is called the *radius vector*.

In all our diagrams it is to be understood, that the planet, or satellite, moves through its orbit in the direction opposite to the motion of the hands of a watch. This is the direction in which all the planets and satellites would appear to move, if viewed from any place on the north side of the planes of their orbits.

The time in which the planet moves from any one point of the orbit through the whole orbit, till it comes to the same point again, is called the planet's *periodic time*.

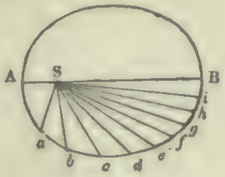
(28.) If we know the mass of the central body, and if we suppose the revolving body to be projected at a certain place in a known direction with a given velocity, the length of the axis major, the excentricity, the position of the line of apses, and the periodic time, may all be calculated. We cannot point out the methods and formulæ used for these, but we may mention one very remarkable result. The length of the axis major depends only upon the velocity of projection, and upon the place of projection, and not at all upon the direction of projection.

(29.) We shall proceed to notice the principle on which the motion of a planet, or satellite, in its orbit, is calculated.

It is plain that this is not a very easy business. We have already explained, that the velocity of the planet in its orbit is not uniform (being greatest when the planet's distance from the sun is least, or when the planet is at perihelion); and it is obvious, that the longitude of the planet increases very irregularly; since, when the planet is near to the sun, its actual motion is very rapid, and, therefore the increase of longitude is extremely rapid; and when the planet is far from the sun, its actual motion is slow, and, therefore, the increase of longitude is extremely slow. The rule which is demonstrated by theory, and which is found to apply precisely in observation, is this:—The areas described by the radius vector are equal in equal times. This is true, whether the force be inversely as the square of the distance from the central body, or be in any other proportion, provided that it is directed to the central body.

(30.) Thus, if in one day a planet, or a satellite, moves from A to *a*, *fig.* 5; in the next day it will move from *a* to *b*, making the area *a* S *b* equal to A S *a*; in the third day it will move from *b* to *c*, making the area *b* S *c* equal to A S *a* or *a* S *b*, and so on.

Fig. 5.



(31.) Upon this principle mathematicians have invented methods of calculating the place of a planet or satellite, at any time for which it may be required. These methods are too troublesome for us to explain here; but we may point out the meaning of two terms which are frequently used in these computations. Suppose, for instance, as in the figure, that the planet, or satellite, occupies ten days in describing the half of its orbit, A *a b c d e f g h i* B, or twenty days in describing the whole orbit; and suppose that we wished to find its place at the end of three days after leaving the perihelion. If the orbit were a circle, the planet would in three days have moved through an angle of 54 degrees. If the excentricity of the orbit were small (that is, if the orbit did not differ much from a circle), the angle through which the planet would have moved would not differ much from 54 degrees. The excentricities of all the orbits of the planets are small; and it is convenient, therefore, to begin with the angle 54° as one which is not very erroneous, but which will require some correction. This angle (as 54°), which is proportional to the time, is called the *mean anomaly*; and the correction which it requires, in order to produce the true anomaly, is called the *equation of the centre*. If we examine the nature of the motion, while the planet moves from A to B, it will be readily seen, that during the whole of that time, the angle really described by the planet is *greater* than the angle which is proportional to the time, or the equation of the centre is to be *added* to the mean anomaly, in order to produce the true anomaly; but while the planet moves in the other half of the orbit, from B to A, the angle really described by the planet is *less* than the angle which is proportional to the time, or the equation of the centre is to be *subtracted from* the mean anomaly, in order to produce the true anomaly.

(32.) The sum of the mean anomaly and the longitude of perihelion is called the *mean longitude* of the planet. It is evident, that if we add the equation of the centre to the mean longitude, while the planet is moving from A to B, or subtract it from the mean longitude, while the planet is moving from A to B, as in (31), we shall form the true longitude.

(33.) The reader will see, that when the planet's true anomaly is calculated, the length of the radius vector can be computed from a knowledge of the properties of the ellipse. Thus the place of the planet, for any time, is perfectly known. This problem has acquired considerable celebrity under the name of Kepler's problem.

(34.) There remains only one point to be explained regarding the undisturbed motion of planets and satellites; namely, the relation between a planet's periodic time and the dimensions of the orbit in which it moves.

Now, on the law of gravitation it has been demonstrated from theory, and it is fully confirmed by observation, that the periodic time does not depend on the excentricity, or on the perihelion distance, or on the aphelion distance, or on any element except the *mean distance* or semi-major axis. So that if two planets moved round the sun, one in a circle, or in an orbit nearly circular, and the other in a very flat ellipse; provided their mean distances were equal, their periodic times would be equal. It is demonstrated also, that for planets at different distances, the relation between the periodic times and the mean distances is the following: The squares of the number of days (or hours, or minutes, &c.) in the periodic times have the same proportion as the cubes of the numbers of miles (or feet, &c.) in the mean distances.

(35.) Thus the periodic time of Jupiter round the sun is 4332·7 days, and that of Saturn is 10759·2 days; the squares of these numbers are 18772289 and 115760385. The mean distance of Jupiter from the sun is about 487491000 miles, and that of Saturn is about 893955000 miles; the cubes of these numbers are 1158496 (20 ciphers), and 7144088 (20 ciphers). On trial it will be found, that 18772289 and 115760385 are in almost exactly the same proportion as 1158496 and 7144088.

(36.) In like manner, the periodic times of Jupiter's third and fourth satellites round Jupiter are 7·15455 and 16·68877 days; the squares of these numbers are 51·1876 and 278·515. Their mean distances from Jupiter are 670080 and 1178560 miles; the cubes of these numbers are 300866 (12 ciphers), and 1667029 (12 ciphers), and the proportion of 51·1876 to 278·515 is almost exactly the same as the proportion of 300866 to 1637029.

(37.) It must however be observed that this rule applies in comparing the periodic times and mean distances, *only* of bodies which revolve round the *same* central body. Thus the rule applies in comparing the periodic times and mean distances of Jupiter and Saturn, because they both revolve round the sun; it applies in comparing the periodic times and mean distances of Jupiter's third and fourth satellites, because they both revolve round Jupiter; but it would not apply in comparing the periodic time and mean distance of Saturn revolving round the sun with that of Jupiter's third satellite revolving round Jupiter.

(38.) In comparing the orbits described by different planets, or satellites, round different centres of force, theory gives us the following law:—The cubes of the mean distances are in the same proportion as the products of the mass by the square of the periodic time. Thus, for instance, the mean distance of Jupiter's fourth satellite from Jupiter is 1178560 miles; its periodic time round Jupiter is 16·68877 days; the mean distance of the earth from the sun is 93726900 miles; its periodic time round the sun is 365·2564 days; also the mass of Jupiter is $\frac{1}{1050}$th the sun's mass. The cubes of the mean distances are respectively 1637029 (12 ciphers), and 823365 (18 ciphers); the products of the squares of the times by the masses are respectively 0·265252 and 133412; and these numbers are in the same proportion as 1637029 (12 ciphers), and 823365 (18 ciphers).

(39.) The three rules—that planets move in ellipses, that the radius vector in each orbit passes over areas proportional to the times, and that the squares of the periodic times are proportional to the cubes of the mean distances,—are commonly called Kepler's laws. They were discovered by Kepler from observation, before the theory of gravitation was invented; they were first explained from the theory by Newton, about the year 1680.

(40.) The last of these is not strictly true, unless we suppose that the central body is absolutely immoveable. This however is evidently inconsistent with the principles which we have laid down in Section I. In considering the motion, for instance, of Jupiter round the sun, it is necessary to consider that, while the sun attracts Jupiter, Jupiter is also attracting the sun. But the planets are so small in comparison with the sun (the largest of them, Jupiter, having less than one-thousandth part of the matter contained in the sun), that in common illustrations there is no need to take this consideration into account. For nice astronomical purposes it is taken into account in the following manner:—The motion which the attraction of Jupiter produces in the sun is less than the motion which the attraction of the sun produces in Jupiter, in the same proportion in which Jupiter is smaller than the sun. If the sun and Jupiter were allowed to approach one another, their rate of approach would be the *sum* of the motions of the sun and Jupiter, and would therefore be greater than their rate of approach, if the sun were not moveable, in the same proportion in which the sum of the masses of the sun and Jupiter is greater than the sun's mass; that is, the rate of approach of the sun and Jupiter, both being free, is the same as the rate of approach would be if the sun were fixed, provided the sun's mass were increased by adding Jupiter's mass to it. Consequently, in comparing the orbits described by different planets round the sun, we must use the rule just laid down, supposing the central force to be the attraction of a mass equal to the sum of the sun and the planet; and thus we get a proportion which is rigorously true: for different planets, or even for different bodies revolving round different centres of force, the cubes of the mean distances are in the same proportion as the products of the square of the periodic time by the sum of the masses of the attracting and attracted body.

SECTION III.—*General Notions of Perturbation; and Perturbation of the Elements of Orbits.*

(41.) We have spoken of the motion of two bodies (as the sun and a planet) as if no other attracting body existed. But, as we have stated in Section I., every planet and every satellite attracts the sun and every other planet and satellite. It is plain now that, as each planet is attracted very differently at different times by the other planets whose position is perpetually varying, the motion is no longer the same as if it was only attracted by the sun. The planets therefore do not move exactly in ellipses; the radius vector of each planet does not pass over areas exactly proportional to the times; and the proportion of the cube of the mean distance to the product of the square of the periodic time by the sum of the masses of the sun and the planet, is not strictly the same for all. Still the disturbing forces of the other planets are so small in comparison with the attraction of the sun, that these laws are very nearly true; and (except for our moon and the other satellites) it is only by accurate observation, continued for some years, that the effects of perturbation can be made sensible.

(42.) The investigation of the effects of the disturbing forces will consist of two parts: the examination into the effects of disturbing forces generally upon the motion of a planet, and the examination into the kind of disturbing force which the attraction of another planet produces. We shall commence with the former; we shall suppose that a planet is revolving round the sun, the sun being fixed (a supposition made only for present convenience), and that some force acts on the planet without acting on the sun (a restriction introduced only for convenience, and which we shall hereafter get rid of).

(43.) The principle upon which we shall explain the effect of this force is that known to mathematicians by the name of *variation of elements*. The planet, as we have said, describes some curve which is not strictly an ellipse, or indeed, any regularly formed curve. It will not even describe the same curve in successive revolutions. Yet its motion may be represented by supposing it to have moved in an ellipse, provided we suppose the elements of the ellipse to have been perpetually altering. It is plain that by this contrivance any motion whatever may be represented. By altering the major axis, the excentricity, and the longitude of perihelion, we may in many different ways make an ellipse that will pass through any place of the planet; and by altering them in some particular proportions, we may, in several ways, make an ellipse in which the direction of motion at the place of the planet shall be the same as the direction of the planet's motion. But there is only one ellipse which will pass exactly through a place of the planet, in which the direction of the motion at that place shall be exactly the same as the direction of the planet's motion, and in which the velocity (in order that a body may revolve in that ellipse round the sun) will be the same as the planet's real velocity. The dimensions and position of this ellipse may be conceived as follows; if at any instant we suppose the disturbing force to cease, and conceive the planet to be as it were projected with the velocity which it happens to have at that instant, the attraction of the sun or central body will cause it to describe the ellipse of which we are speaking. We shall in future mention this by the name of the *instantaneous ellipse*.

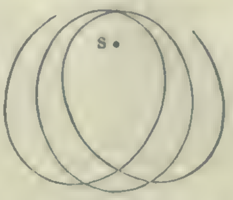
(44.) If the disturbing force ceases, the planet continues to revolve in the same ellipse, and the permanent ellipse coincides with the instantaneous ellipse corresponding to the instant when the disturbing force ceases.

(45.) If the disturbing force continues to act, the dimensions of the instantaneous ellipse are continually changing: but in the course of a single revolution (even for our moon), the dimensions alter so little, that the motion in the instantaneous ellipse corresponding to any instant during that revolution will very nearly agree with the real motion during that revolution.

We shall now consider the effects of particular forces in altering the elements.

(46.) (I.) Suppose that the disturbing force is always directed to the central body. The effect of this would be nearly the same as if the attraction, or the mass of the central body, was increased. The result of this on the dimensions of the orbit will be different according to the part of the orbit where it begins to act, and may be gathered from the cases to be mentioned separately hereafter (we do not insist on it at present, as there is no instance in the planetary system of such sudden commencement of force). But at all events the relation between the mean distance and the periodic time will not be the same as before; the time will be less for the same mean distance, or the mean distance greater for the same periodic time than if the disturbing force did not act (38). If the disturbing force is always directed from the central body, the effect will be exactly opposite. If the disturbing force does not alter, except with the planet's distance, the planet will at every successive revolution describe an orbit of the same size. For, as we have stated (29), the radius vector will in equal times pass over equal areas; and mathematicians have proved that, if the variation of force depends only on the distance, the velocity of the planet will depend only on the distance; and the consideration which determines the greater or least distance of the planet is, that the planet, moving with the velocity which is proper to the distance, cannot describe the proper area in a short time, unless it move in the direction perpendicular to the radius vector. This consideration will evidently give the same values for the greatest and least distances at every revolution. It may happen that all the greatest distances will not be at the same place; the body may describe such an orbit as that in *fig.* 6.

Fig. 6.



(47.) (II.) If, however, the disturbing force directed to the central body increases gradually and constantly during many revolutions, there is no difficulty in seeing that the planet will at every revolution be drawn nearer to the central body, and thus it will move, at every succeeding revolution, in a smaller orbit than at the preceding one; and will consequently perform its revolution in a shorter time. If the disturbing force directed to the central body diminishes, the orbit will become larger, and the periodic time longer. In the same manner, if the disturbing force is directed from the central body, a gradual increase of the disturbing force will increase the dimensions of the orbit and the periodic time, and a gradual diminution of the disturbing force will diminish the dimensions of the orbit and the periodic time.

(48.) (III.) Suppose that the disturbing force acts always in the direction in which the planet is moving. The reader might imagine at first sight that this would shorten the time of revolution. The effect, however, is exactly opposite; for in *fig.* 2, if the planet be projected from A, the reason that the sun's attraction is able to pull the planet in at C and make it approach to itself is, that the velocity of the planet is so small as to allow the force to curve the orbit much. If the velocity were greater, the orbit—as we have said in (25)—would be *less curved* in every part, and would therefore pass on the *outside* of the orbit A C D E F. The effect then of a force in the direction of the planet's motion, which increases the planet's velocity, is to increase the size of its orbit; and the bigger the orbit is, the longer is the time of revolution. If the force acts continually, the time of revolution lengthens continually. If the disturbing force acts in the direction opposite to that in which the planet is moving, the effect is to make the orbit smaller, and to make the time of revolution shorter. The retardation produced by motion through extremely thin air is of this kind: it is found that a comet (known by the name of Encke's comet) which moves in an ellipse, whose length is not much greater than the diameter of Mars' orbit, performs every new revolution in a shorter time than the preceding one; and we infer from this circumstance that it experiences some resistance in its motion.

(49.) (IV.) There is one consideration of great importance in the estimation of the effects mentioned in (II.) and (III.). The alteration of the dimensions of the orbit produces an alteration in the periodic time, and this alters the planet's *mean motion*, or the number of degrees by which the mean longitude is increased in a given time (suppose one year). The effects of these alterations are added together at every successive revolution, and thus may produce an alteration in the planet's mean longitude (which differs from the true longitude only by the equation of the centre) that is vastly more conspicuous than the alteration in the dimensions of the orbit. Suppose, for instance, that a disturbing force acted on a planet (either a constant force in the direction of its motion, or a variable force in the direction of the radius vector), such as to increase the mean distance by $\frac{1}{10000}$th part in 100 revolutions of the planet. This alteration of the planet's distance from the sun could hardly be discovered by the nicest observations. But as the mean distance has been altered in the proportion of 10000 : 10001, the periodic time will have been altered in the proportion of 10000 : 10001½ nearly, or the mean motion will have been altered in the proportion of 10001½ to 10000, or 1 : 0·99985 nearly. If this alteration has gone on uniformly, we may suppose the whole motion in the 100 revolutions to have been nearly the same as if the planet had moved with a mean motion, whose value is half way between the values of the first and the last, or 0·999925 × the original mean motion. Therefore, at the time when we should expect the planet to have made 100 revolutions, it will only have made 99·9925 revolutions, or will be *behind* the place where we expected to see it by 0·0075 revolution, or nearly three degrees; a quantity which could not fail to be noticed by the coarsest observer. To use a borrowed illustration, the alteration of the mean distance in an orbit produces the same kind of effect as the alteration of the length of a clock pendulum which, though so small as to be insensible to the eye, will in a few days produce a very great effect on the time shown by the clock.

(50.) (V.) Now, suppose the orbit of the planet or satellite to be an ellipse; and suppose a disturbing force directed to the central body to act upon the planet, &c., only when it is near its perihelion or perigee, &c. In *fig.* 7, let A B be the curve in which the planet is moving, and let the dotted line B C D A represent the orbit in which it would have moved if no disturbing force had acted, C being the place of perihelion. At B let the disturbing force, directed towards S, begin to act, and let it act for a little while, and then cease. The planet is at that place approaching toward the sun, and the direction of its motion makes an acute angle with S B. It is evident that the disturbing force, which draws the planet more rapidly towards the sun without otherwise affecting its motion, will cause it to move in a direction that makes a more acute angle with S B. The part of the new path, therefore, which is nearest to the sun (that is, the new perihelion) will be farther from B than the perihelion C of the orbit in which the planet would have moved. The reader's conception of this will be facilitated by supposing the orbit, instead of a curve, to be a straight line, as B C in *fig.* 7*, and the place of perihelion to be determined by letting fall a perpendicular S C from the sun upon the line, when it will be seen that if the disturbing force, acting towards S for a short time at B, changes the path of the planet from the direction B C to B *c*, the distance of the foot of the perpendicular S *c* from B is greater than that of S C. With a curved orbit the result is just the same. In other words, the planet, instead of describing B C *fig.* 7, will, in consequence of the action of the disturbing force, describe B *c*; and the place of perihelion, instead of C, will be *c*, a point more distant from B than C is. Now, if the disturbing force should not act again, the planet would move in an ellipse *c d b*, and the line of apses, instead of C S D, would be *c* S *d*. The line of apses has, therefore, twisted round in the same angular direction as that in which the planet was going; and this is expressed by saying that *the line of apses progresses.* If, after passing *c*, the disturbing force should again act for a little while,—at *e* for instance,—the recess of the planet from the sun would be diminished; its path would be more nearly perpendicular to the radius vector; and, therefore, the inclination of the path would be such as corresponds to a smaller distance from perihelion than the planet really has; that is, when the planet leaves *e*, the inclination of its path to the radius vector is greater than it would have been if the planet had continued to move in the orbit *c d b*, but is the same as if its perihelion had been at some such situation as *f*, supposing no disturbing force to act. Now let the disturbing force cease entirely to act, and the planet, which at *e* is moving as if it had come from the perihelion *f*, will continue to move as if it had come from the perihelion *f*; it will proceed, therefore, to describe an elliptic orbit in which *f* S *g* is the line of apses: the line of apses has been twisted round in the same direction as before, or the line of apses has still progressed. The effect, then, of a disturbing force directed to the central body before and after passing the perihelion, is to make the line of apses progress.*

Fig. 7.

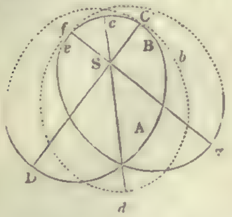


Fig. 7*

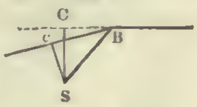

(51.) In the same manner, it will be seen, that the effect of a disturbing force, directed from the central body before and after passing the perihelion, is to make the line of apses regress.

(52.) The motion of the planet, subject to such forces as we have mentioned, would be *nearly* the same as if it was revolving in an elliptic orbit, and this elliptic orbit was at the same time revolving round its focus, turning in the same direction as that in which the planet goes round, and always carrying it on its circumference. And this is the easiest way of representing to the mind the *general effect* of this motion; the *physical cause* is to be sought in such explanations as that above.

(53.) (VI.) Suppose a disturbing force directed to the centre, to act upon the planet when it is near aphelion. As the planet is going towards aphelion it is receding from the sun. The effect of the disturbing force is to diminish the rate of recess from the sun; and, therefore, to increase the inclination of the planet's path to the radius vector. The aphelion is the place where the planet's path is perpendicular to the radius vector. The effect of the disturbing force, then, which increases the inclination of the planet's path to the radius vector, will be to make that path perpendicular to the radius vector sooner than if the disturbing force had not acted. That is, the planet will be at aphelion sooner than it would have been if no disturbing force had acted. The aphelion has, as it were, gone backwards to meet the planet. If the disturbing force should entirely cease, the planet will move in an elliptic orbit, of which this new aphelion would be the permanent aphelion. The line passing through the aphelion has, therefore, twisted in a direction opposite to the planet's motion, or *the line of apses has regressed.* After passing aphelion, if the disturbing force still continues to act, the planet's approach to the sun will be quickened by the disturbing force; and, therefore, after some time, the planet's rate of approach will be greater than that corresponding, in an undisturbed orbit, to its actual distance from aphelion, and will be equal to that corresponding in an undisturbed orbit to a greater distance from aphelion. If, now, the disturbing force ceases, the planet, moving as if it came in an undisturbed orbit from an imaginary aphelion, will continue to move as if it came from that imaginary aphelion; and that imaginary aphelion having been at a greater distance behind the planet than the real aphelion, its place will be represented by saying that the line of apses has still regressed. The effect, then, of a disturbing force directed to the central body, before and after passing aphelion, is to make the line of apses regress.

(54.) In the same manner it will be seen, that the effect of a disturbing force, directed from the central body, before and after passing the aphelion, is to make the line of apses progress.

(55.) (VII.) Since a disturbing force, directed to the central body, or one directed from the central body, produces opposite effects with regard to the motion of the line of apses, according as it acts near perihelion or near aphelion, it is easy to perceive that there must be some place between perihelion and aphelion, where the disturbing force, directed to the central body, will produce no effect on the position of the line of apses. It is found by accurate investigation, that this point is the place where the radius vector is perpendicular to the line of apses.*

(56.) (VIII.) The effects mentioned above are greatest when the excentricity is small. Let us compare the two orbits A C B in *fig.* 8 and A C B in *fig.* 9, in one of which the excentricity is great and in the other small: suppose the disturbing force to act for a short time at the perihelion C, and to be nearly equal in the two orbits, so as to deflect the new path C *d* from the old orbit C B by equal angles in

Fig. 8.

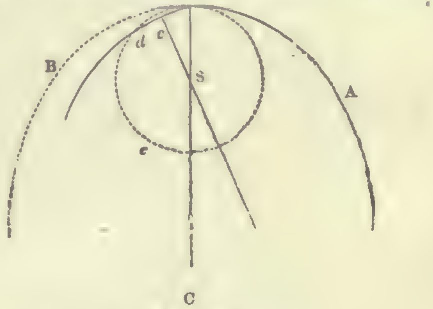

Fig. 9.

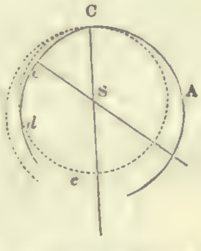


---

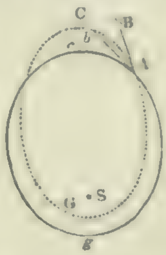
* This result, and those which follow immediately, may be inferred from the construction in Newton's 'Principia,' book i., sect. 3, prop. xvii. If we assume (as we suppose in all these investigations) the excentricity to be small, the disturbing force directed to the sun will not sensibly alter the planet's velocity, but will change the direction of its path at P, the place of action (in Newton's figure); the length of P H, therefore, will not be altered (since that length depends only on the velocity), but its position will be altered, the position of P H being determined by making the angle R P H equal to the supplement of R P S. On trying the effects of this in different positions of P, and observing that the immediate effect of a disturbing force directed to the centre is to increase the rate of approach, or to diminish the rate of receding, and that the effect of a force directed from the centre is the opposite, all the cases in the text will be fully explained.

* To the reader who is familiar with Newton's 'Principia,' sect. 3, the following demonstration will be sufficient: The disturbing force, which is entirely in the direction of the radius vector, will not alter the area described in a given time, and, therefore, will not alter the *latus rectum* (to the square root of which the area is proportional). But half the *latus rectum* of the undisturbed orbit is the radius vector at the supposed place of action of the disturbing force (since that radius vector is supposed perpendicular to the major axis). Therefore, half the *latus rectum* of the new orbit is the radius vector at the point in question; and, consequently, the radius vector, at the point in question, is perpendicular to the major axis in the new orbit; but it was so in the undisturbed orbit; and, therefore, the major axes in the new orbit and the undisturbed orbit coincide.

the two cases; with centre S describe the circle C *d e*. Then it is evident that the very excentric orbit C B in *fig.* 8 is widely separated from the circle C *d e*, and therefore, when it is bent through a given angle to the position C *d*, it will intersect the circle at a point *d* not distant from C. In *fig.* 9, on the contrary, the orbit C B is not widely separated from the circle, and therefore, when it is bent through a given angle, its intersection *d* will be distant from C. Now the new perihelion *c* will be found, in both cases, by bisecting C *d*; and, therefore, its change of position in *fig.* 8, where the orbit is very excentric, is much less than in *fig.* 9, where the excentricity is small. Or we may state it thus: The alteration of the place of perihelion, or aphelion, depends on the proportion which the alteration in the approach or recess produced by the disturbing force bears to the whole approach or recess; and is therefore greatest when the whole approach or recess is least; that is, when the orbit is little excentric.

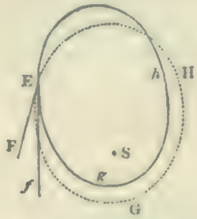
(57.) (IX.) To judge of the effect which a disturbing force, directed to the sun, will produce on the excentricity of a planet's orbit, let us suppose the planet to have left its perihelion, and to be moving towards aphelion, and, consequently, to be receding from the sun, and now let the disturbing force act for a short time. This will cause it to recede from the sun more slowly than it would have receded without the action of the disturbing force; and consequently, the planet, without any material alteration in its velocity,—and, therefore, without any material alteration in the major axis of its orbit (28),—will be moving in a path more inclined to the radius vector than if the disturbing force had not acted. The planet may, therefore, be considered as projected from the point A, *fig.* 10, in the direction A *b* instead of A B, in which it was moving; and, therefore, instead of describing the orbit A C G, in which it was moving before, it will describe an orbit A *c g*, more resembling a circle, or less excentric than before. The effect, therefore, of a disturbing force directed to the centre, while a planet is moving from perihelion to aphelion, is to diminish the excentricity of the orbit.

Fig. 10.



(58.) If we suppose the planet to be moving from aphelion to perihelion, it is approaching to the sun; the disturbing force directed to the sun makes it approach more rapidly; its path is therefore less inclined to the radius vector than it would have been without the disturbing force; and this effect may be represented by supposing that at E, *fig.* 11, instead of moving in the direction E F in which it was moving, the planet is projected in the direction E *f*. Instead therefore of describing the ellipse E G H, in which it was moving before, it will describe such an ellipse as E *g h*, which is more excentric than the former. The effect therefore of a disturbing force directed to the centre, while a planet is moving from aphelion to perihelion, is to increase the excentricity of the orbit.

Fig. 11.



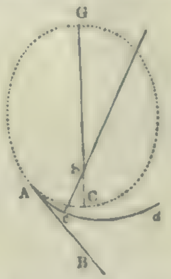
(59.) In a similar manner it will appear, that the effect of a disturbing force, directed from the centre, is to increase the excentricity as the planet is moving from perihelion to aphelion, and to diminish it as the planet moves from aphelion to perihelion.

(60.) (X.) Let us now lay aside the consideration of a force acting in the direction of the radius vector, and consider the effect of a force acting perpendicularly to the radius vector, in the direction in which the planet is moving. And first, its effect on the position of the line of apses.

(61.) If such a force act at one of the apses, either perihelion or aphelion, for a short time, it is clear that its effect will be represented by supposing that the velocity at that apse is suddenly increased, or that the velocity with which the planet is projected from perihelion is greater than the velocity with which it would have been projected if no disturbing force had acted. This will make no difference in the position of the line of apses; for with whatever velocity the planet is projected, if it is projected in a direction perpendicular to the radius vector (which is implied in our supposition, that the place where the force acts was an apse in the old orbit), the place of projection will infallibly be an apse in the new orbit: and the line of apses, which is the line drawn from that point through the sun, will be the same as before.

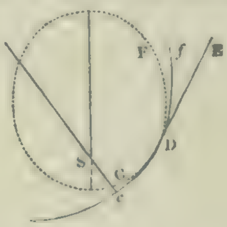
(62.) But if the force act for a short time before the planet reaches the perihelion, its principal * effect will be to increase its velocity; the sun's attraction will therefore have less power to curve its path (25); the new orbit will be, in that part, exterior to the old one. In *fig.* 12, we must therefore suppose that the planet, after leaving A, where the force has acted to accelerate its motion, instead of describing the orbit A C G, proceeds to describe the orbit A *c d*, which at A has the same direction (or has the same tangent A B) as the orbit A C G. It is plain now that *c* is the part nearest to the sun, or *c* is the perihelion: and it is evident here, that the line of apses has altered its position from S C to S *c*, or has twisted in a direction opposite to the angular motion of the planet, or has regressed.

Fig. 12.



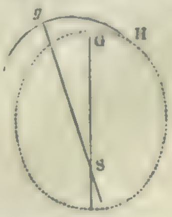
(63.) If the force act for a short time after the planet has passed perihelion, as at D, in *fig.* 13, the planet's velocity is increased there, and the path described by the planet is D *f*, instead of D F, having the same direction at D (or having the same tangent D E), but less curved, and therefore exterior to D F. If now we conceive the planet to have received the actual velocity with which it is moving in D *f*, from moving without disturbance in an elliptic orbit *c* D *f* (which is the orbit that it will now proceed to describe, if no disturbing force continues to act), it is evident that the part *c* D must be described with a greater velocity than C D, inasmuch as the velocity at D from moving in *c* D is greater than the velocity from moving in C D; *c* D is therefore less curved than C D, and therefore exterior to it (since it has the same direction at D); and then the perihelion is some point in the position of *c*, and the line of apses has changed its direction from S C to S *c*, or has twisted round in the same direction in which the planet is moving, or has progressed.

Fig. 13.



(64.) If the force act for a short time before passing the aphelion, it will be seen in the same manner that the line of apses is made to progress. It is only necessary to consider that (as before) the new orbit has the same direction at the point H, *fig.* 14, where the force has acted, as the old one, but is less curved, and therefore exterior to it; and the aphelion, or point most distant from the sun, is *g* instead of G, and the position of the line of apses has shifted from S G to S *g*. If the force act after the planet has passed the aphelion, as at K, *fig.* 15, the orbit in which we must conceive the planet to have come, in order to have the increased velocity, must be *g* K exterior to G K; the point most

Fig. 14.

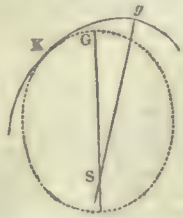


---

* It is supposed here, and in all our investigations, that the excentricity of the orbit is small, and, consequently, that a force perpendicular to the radius vector produces nearly the same effect as a force acting in the direction of a tangent to the ellipse.

distant from the sun must be g instead of G, and the line of apses must have changed from S G to S g, or must have regressed.

Fig. 15.



(65.) Collecting these conclusions,* we see that, if a disturbing force act perpendicularly to the radius vector, in the direction in which the planet is moving, its action, while the planet passes from perihelion to aphelion, causes the line of apses to progress; and its action, while the planet passes from aphelion to perihelion, causes the apses to regress.

(66.) By similar reasoning, if the direction of the disturbing force is opposite to that in which the planet is moving, its action, while the planet passes from perihelion to aphelion, causes the line of apses to regress, and while the planet passes from aphelion to perihelion causes the apses to progress.

(67.) (XI.) For the effect on the excentricity: suppose the disturbing force, increasing the velocity, to act for a short time at perihelion; the effect is the same as if the planet were projected from perihelion with a greater velocity than that which would cause it to describe the old orbit. The sun's attraction therefore will not be able to pull it into so small a compass as before; and at the opposite part of its orbit, that is, at aphelion, it will go off to a greater distance than before; but as it is moving without disturbance, and, therefore, in an ellipse, it will return to the same perihelion. The perihelion distance therefore remaining the same, and the aphelion distance being increased, the inequality of these distances is increased, and the orbit therefore is made more excentric. Now, suppose the force increasing the velocity to act at aphelion. Just as before, the sun's attraction will be unable to make the planet describe an orbit so small as its old orbit, and the distance at the opposite point (that is, at perihelion) will be increased; but the planet will return to the same aphelion distance as before. Here, then, the inequality of distances is diminished, and the excentricity is diminished.

(68.) Thus we see that a disturbing force, acting perpendicularly to the radius vector, in the direction of the planet's motion, increases the excentricity if it acts on the planet near perihelion, and diminishes the excentricity if it acts on the planet near aphelion. And, similarly, if the force acts in the direction opposite to that of the planet's motion, it diminishes the excentricity by acting near perihelion, and increases it by acting near aphelion.

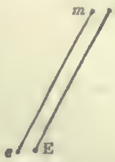
(69.) (XII.) In all these investigations, it is supposed that the disturbing force acts for a very short time, and then ceases. In future, we shall have to consider the effect of forces, which act for a long time, changing in intensity, but not ceasing. To estimate their effect we must suppose the long time divided into a great number of short times; we must then infer, from the preceding theorems, how the elements of the *instantaneous ellipse* (43) are changed in each of these short times by the action of the force, which is then disturbing the motion; and we must then recollect, that the instantaneous ellipse, at the end of the long time under consideration, will be the same as the permanent ellipse in which the planet will move. if the disturbing force then ceases to act (43), and that it will, at all events, differ very little from the curve described in the next revolution of the planet, even if the disturbing force continue to act. (41.)

SECTION IV.—*On the Nature of the Force disturbing a Planet or Satellite, produced by the Attraction of other Bodies.*

(70.) Having examined the effects of disturbing forces upon the elements of a planet's or satellite's orbit, we have now to inquire into the kind of the disturbing force which the attraction of another body produces. The inquiry is much simpler than might at first sight be expected; and this simplicity arises, in part, from the circumstance that (as we have mentioned in (6)) the attraction of a planet upon the sun is the same as its attraction upon another planet, when the sun and the attracted planet are equally distant from the attracting planet.

(71.) First, then, we have to remark, that the disturbing force is not the whole attraction. The sun, for instance, attracts the moon, and disturbs its elliptic motion round the earth; yet the force which disturbs the moon's motion is not the whole attraction of the sun upon the moon. For the effect of the attraction is to move the moon from the place where it would otherwise have been; but the sun's attraction upon the earth also moves the earth from the place where it would otherwise have been; and if the alteration of the earth's place is exactly the same as the alteration of the moon's place, the relative situation of the earth and moon will be the same as before. Thus, if, in *fig.* 16, any attraction carries the earth from E to e, and carries the

Fig. 16.



moon from M to m, and if E e is equal and parallel to M m, then $e\,m$, which is the distance of the earth and moon, on the supposition that the attraction acts on both, is equal to E M, which is their distance, on the supposition that the attraction acts on neither; and the line $e\,m$, which represents the direction in which the moon is seen from the earth, if the attraction acts on both, is parallel to E M, which represents the direction in which the moon is seen from the earth, if the attraction acts on neither. The distance therefore of the earth and moon, and the direction in which the moon is seen from the earth, being unaltered by such a force, their relative situation is unaltered. An attraction, therefore, which acts equally, and in the same direction, on both bodies, does not disturb their relative motions.

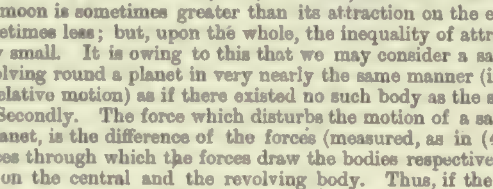
From this we draw the two following important conclusions:—

(72.) Firstly. A planet may revolve round the sun, carrying with it a satellite; and the satellite may revolve round the planet in nearly the same manner as if the planet was at rest. For the attraction of the sun on the planet is nearly the same as the attraction of the sun on the satellite. It is true that they are not exactly the same, and the effects of the difference will soon form an important subject of inquiry; but they are, upon the whole, very nearly the same. The moon is sometimes nearer to the sun than the earth is, and sometimes farther from the sun; and, therefore, the sun's attraction on the moon is sometimes greater than its attraction on the earth, and sometimes less; but, upon the whole, the inequality of attractions is very small. It is owing to this that we may consider a satellite as revolving round a planet in very nearly the same manner (in respect of relative motion) as if there existed no such body as the sun.

(73.) Secondly. The force which disturbs the motion of a satellite, or a planet, is the difference of the forces (measured, as in (4), by the spaces through which the forces draw the bodies respectively) which act on the central and the revolving body. Thus, if the moon is between the sun and the earth, and if the sun's attraction in a certain time draws the earth 200 inches, and in the same time draws the moon 201 inches, then the real disturbing force is the force which would produce in the moon a motion of one inch from the earth.

(74.) In illustrating the second remark, we have taken the simplest case that can well be imagined. If, however, the moon is in any other situation with respect to the earth, some complication is introduced. Not only is the moon's distance from the sun different from the earth's distance, (which according to (9) produces an inequality in the attractions upon the earth and moon,) but also the direction in which the attraction acts on the earth is different from the direction in which it acts on the moon, (inasmuch as the attraction always acts in the direction of the line drawn from the attracted body to the attracting body; and the lines so drawn from the earth and moon to the sun are in different directions.) The same applies in every respect to the perturbation which one planet produces in the motion of a second planet round the sun, and which depends upon the difference in the first planet's attractions upon the sun and upon the second planet. To overcome this difficulty we must have recourse to geometrical considerations. In *fig.* 17, let B_1 be a body revolving about A, and let C be another body whose attraction disturbs the motion of B_1 round A The attraction of C will in a certain time draw A to a; it will in the same time draw B_1 to b_1. Make $B_1\,d_1$ equal and parallel to A a; then $a\,d_1$ will be equal and parallel to A B_1. Now if the force upon B_1 were such as to draw it to d_1, the motion of B_1 round A would not be disturbed by that force. But the force upon B_1 is really such as to draw it to b_1. The real disturbing force then may be represented as a force which draws the revolving body from d_1 to b_1. If, instead of supposing the revolving body to be at B_1 we suppose it at B_2, and if the attraction of C would draw it through $B_2\,b_2$ while it draws A through A a, then (in the same manner, making $B_2\,d_2$ equal and parallel to A a) the real disturbing force may be represented by a force which in the same time would draw B_2 through $d_2\,b_2$.

Fig. 17.

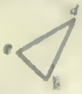


---

* These conclusions, and those that follow, will be easily inferred from Newton's construction, Prop. XVII., by observing, that an increase of the velocity increases the length of P H in Newton's figure without altering its position.

(75.) Both the magnitude and the direction of this force are continually varying, and we must, if possible, find a convenient way of representing it. We shall have recourse here to the "compositon of motion." In *fig.* 18, if $d\,b$ represent the space through which a force has drawn a body in a certain time, the same effect may be produced by two forces of which one would in the same time draw the body from d to e, and the other would in the same time draw the body from e to b. And this is true whatever be the directions and lengths of $d\,e$ and $e\,b$, provided that with $d\,b$ they form a triangle. To accommodate the investigations of this Section to those of Section III., we will suppose $d\,e$ perpendicular to the radius vector, and $e\,b$ parallel to the radius vector. In *fig.* 17, draw $d\,e$ perpendicular to A B or $a\,d$, and $e\,b$ parallel to A B or $a\,d$; and now we can say: the disturbing force produced by the attraction of C is a force represented by $d\,e$ perpendicular to the radius vector, and a force represented by $e\,b$ in the direction of the radius vector.

Fig. 18.



(76.) We now want nothing but estimations of the magnitudes of these forces in order to apply the investigations of Section III. For the present we shall content ourselves with pointing out some of the most interesting cases.

(77.) I. Let the disturbing body be exterior to the orbit of the disturbed body: (this applies to the disturbance of the moon's motion produced by the sun's attraction, the disturbance of the earth's motion by Jupiter's attraction, the disturbance of the motion of Venus by the earth's attraction, &c.:) and first, let the revolving body B be between the disturbing body C and the central body A (as in *fig.* 19.). If the attraction of C will in a certain time draw A to a, it will in the same time draw B to b, where B b is much greater than A a. Take B d equal to A a, then $d\,b$ is the effect of the disturbing force, which tends to draw B further from A. In this case then, the disturbing force is entirely in the direction of the radius vector, and directed *from* the central body. This is the greatest disturbing force that can be produced by C.

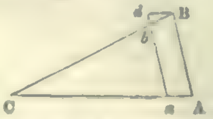
Fig. 19.

(78.) II. Let C A B (*fig.* 20) be in the same straight line, but let B be on the side of A, opposite to C. In this case B b is less than A a; and if B d is taken equal to A a, the disturbing force represented by $d\,b$ will be entirely in the direction of the radius vector, and directed from the central body. This case is particularly deserving of the reader's consideration, as the *effectual disturbing* force is exactly opposite to the attraction which C actually exerts upon B.

Fig. 20.

(79.) III. The disturbing force in the case represented in *fig.* 19, is much greater than that in the case of *fig.* 20, except C be very distant. Thus, suppose A B to be half of A C. In the first case, the attraction upon B (by the law of gravitation) is four times as great as the attraction upon A, and therefore the disturbing force (which is the difference of the forces on A and B) is three times as great as the attraction upon A. In the second case, the distance of B is $\frac{3}{2}$ of the distance of A, and therefore the attraction upon B is $\frac{4}{9}$ of the attraction upon A, and the disturbing force is $\frac{5}{9}$ of the attraction upon A. The disturbing force in the first case is, therefore, greater than in the second case, in the proportion of 3 to $\frac{5}{9}$, or 27 to 5. This remark applies to nearly all the cases of planetary disturbance where the disturbing planet is exterior to the orbit of the disturbed planet, the ratio between these distances from the sun being a ratio of not very great inequality. But it scarcely applies to the moon. For the sun's distance from the earth is nearly 400 times the moon's distance: consequently when the moon is between the sun and the earth, the attraction of the sun on the moon is $(\frac{400}{399})^2 \times$ the attraction of the sun on the earth, or $\frac{160000}{159201}$ parts of the sun's attraction on the earth, and the disturbing force therefore is $\frac{799}{159201}$ parts of the sun's attraction on the earth; but when the moon is on that side farthest from the sun, the sun's attraction on the moon is $(\frac{400}{401})^2$ or $\frac{160000}{160801}$ parts of the sun's attraction on the earth, and the disturbing force is $\frac{801}{160801}$ parts of the sun's attraction on the earth, which is very little less than the former. The effects of the difference are, however, sensible.

Fig. 21.



(80.) IV. Suppose B, *fig.* 21, to be in that part of its orbit which is at the same distance from C as the distance of A from C. The attraction of C upon the two other bodies, whose distances are equal, will be equal, but not in the same direction. B b, therefore, will be equal to A a. But since C B is also equal to C A, it is evident that $a\,b$ will be parallel to A B, and therefore b will be in the line $a\,d$. Consequently in this case also the disturbing force will be entirely in the direction of the radius vector; but here, unlike the other cases, the disturbing force is directed *towards* the central body. The magnitude of the disturbing force bears the same proportion to the whole attraction on A which $b\,d$ bears to B b, or A B to A C. Thus, in the first numerical instance taken above, the disturbing force in this part of the orbit is $\frac{1}{2}$ of the attraction on A: and in the second numerical instance, the disturbing force is $\frac{1}{400}$ of the attraction on A. It is important to observe that in both instances the disturbing force, when wholly directed *to* the centre, is much less than either value of the disturbing force when wholly directed *from* the centre: in the latter instance it is almost exactly one-half.

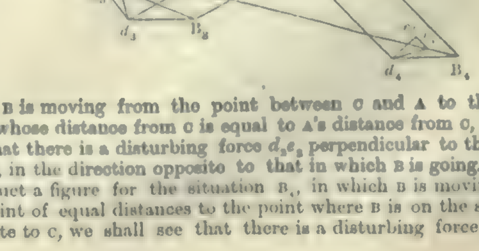
81. When the disturbing body is distant, the point of the orbit which we have here considered is very nearly that determined by drawing A B perpendicular to C A.

(82.) V. When C is distant (as in the case of the moon disturbed by the sun), the disturbing forces mentioned in (III.) and (IV.) are nearly proportional to the distance of the moon from the earth. For the force mentioned in (IV.) this is exactly true, whether C be near or distant, because (as we have found) the disturbing force bears the same proportion to the whole attraction on A which A B bears to A C. With regard to the force mentioned in (III.): if we suppose the moon's distance from the earth to be $\frac{1}{400}$ of the sun's distance, the disturbing force when the moon is between the earth and the sun is $\frac{799}{159201}$ parts of the sun's attraction on the earth, or nearly $\frac{1}{200}$th part. But if we suppose the moon's distance from the earth to be $\frac{1}{200}$th of the sun's distance, the attraction on the moon (when between the earth and the sun) would be $(\frac{200}{199})^2$ or $\frac{40000}{39601}$ parts of the attraction on the earth; the disturbing force or the difference of attractions on the earth and moon, would be $\frac{399}{39601}$, or nearly $\frac{1}{100}$th part of the sun's attraction on the earth. Thus, on doubling the moon's distance from the earth, the disturbing force is nearly doubled: and in the same manner, on altering the distance in any other proportion, we should find that the disturbing force is altered in nearly the same proportion.

(83.) VI. If, while the moon's distance from the earth is not sensibly altered, the earth's distance from the sun is altered, the disturbing force is diminished very nearly in the same ratio in which the cube of the sun's distance is increased. For if the sun's distance is 400 times the moon's distance, and the moon between the earth and the sun, we have seen that the disturbing force is nearly $\frac{1}{200}$th part of the sun's attraction on the earth *at that distance of the sun.* Now, suppose the sun's distance from the earth to be made 800 times the moon's distance, or twice the former distance: the sun's distance from the moon will be 799 times the moon's distance, or $\frac{799}{400}$ parts of the sun's former distance from the earth; the attractions on the earth and moon respectively will be $\frac{1}{4}$ and $\frac{160000}{638401}$ parts of the former attraction on the earth: and the disturbing force, or the difference between these, will be $\frac{1599}{2553604}$, or nearly $\frac{1}{1600}$th part of the former attraction of the earth. Thus, on doubling the sun's distance, the disturbing force is diminished to $\frac{1}{8}$th part of its former value; and a similar proposition would be found to be true if the sun's distance were altered in any other proportion.

(84.) VII. Suppose B to have moved from that part of its orbit where its distance from C is equal to A's distance from C, towards the part where it is between A and C. Since at the point where B's distance from C is equal to A's distance from C, the disturbing force is in the direction of the radius vector, and directed *towards* A, and since at the point where B is between A and C, the disturbing force is in the direction of the radius vector, but directed *from* A, it is plain that there is some situation of B, between these two points, in which there is no disturbing force at all in the direction of the radius vector. On this we shall not at present speak further: but we shall remark that there is a disturbing force perpendicular to the radius vector, at every such intermediate point. This will be easily seen from the second case of *fig.* 17. On going through the reasoning in that place it will appear that, between the two points that we have mentioned, there is always a disturbing force d_2e_2 perpendicular to the radius vector, and in the same direction in which the body is going. If now we construct a similar figure for the situation B_3, *fig.* 22, in which B is moving from the point between C and A to the other point whose distance from C is equal to A's distance from C, we shall find that there is a disturbing force d_3e_3 perpendicular to the radius vector, in the direction opposite to that in which B is going. If we construct a figure for the situation B_4, in which B is moving from the point of equal distances to the point where B is on the side of A opposite to C, we shall see that there is a disturbing force perpen-

Fig. 22.

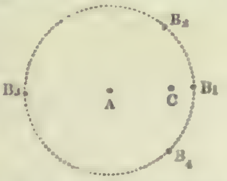


dicular to the radius vector, in the same direction in which B is going; and in the same manner, for the situation B_1 in *fig.* 17, where B is moving from the point on the side of A opposite C to the next **point of equal distances, there is a disturbing force perpendicular** to the radius vector, in the direction opposite to that in which B is going.

(85.) The results of all these cases may be collected thus. The disturbing body being exterior to the orbit of the revolving body, there is a disturbing force in the direction of the radius vector only, directed *from* the central body, at the points where the revolving body is on the same side of the central body as the disturbing body, or on the opposite side (the force in the former case being the greater), and **directed *to* the central body, at each of the places where the distance** from the disturbing body is equal to the distance of the central body from the disturbing body. The force directed to the central body at the latter points, is, however, much less than the force directed from it at the former. Between the adjacent pairs of these four points there are four other points, at which the disturbing force in the direction of the radius vector is nothing. But while the revolving body is moving from one of the points, where it is on the same side of the central body as the disturbing body, or on the opposite side, to one of the equidistant points, there is always a disturbing force perpendicular to the radius vector tending to retard it; and while it is moving from one of the equidistant points to one of the points on the same side of the central body as the disturbing body, or the opposite, there is a disturbing force perpendicular to the radius vector tending **to accelerate it.**

(86.) VIII. Now, let the disturbing body be supposed interior to the orbit of the revolving body (as, for instance, when Venus disturbs the motion of the earth). **If B is in the situation B_1, *fig.* 23, the**

Fig. 23.



attraction of C draws A strongly towards B_1, and B_1 strongly towards A, and, therefore, there is a very powerful disturbing force drawing B_1 towards A. If B is in the situation B_3, the attraction of C draws A strongly from B_3, and draws B_3 feebly towards A; therefore, there is a small disturbing force drawing B_1 from A. At some intermediate points the disturbing force in the direction of the radius vector is nothing. With regard to the disturbing force perpendicular to the radius **vector: if A C is greater than ½ A B_1, it will** be possible to find two points, B_2 and B_4, whose distance from C is **equal to the** distance of A from C, and there the disturbing force perpendicular to the radius vector is nothing (or the whole disturbing force is in the direction of the radius vector). While B moves from the position B_1 to B_2, it will be seen by such reasoning as that of (75) and (84), that the disturbing force, perpendicular to the radius vector, retards B's motion; while B moves from B_2 to B_3, it **accelerates B's motion; while B moves from B_3 to B_4 it retards B's motion; and while B moves from B_4 to B_1, it accelerates B's motion. But if A C is less than ½ A B_1, there are no such points, B_2 B_4, as we have spoken of; and the disturbing force perpendicular to the radius vector, accelerates B as it moves from B_1 to B_3, and retards B as it moves from B_3 to B_1.**

We shall now proceed to apply these general principles to particular cases.

SECTION V.—*Lunar Theory.*

(87.) The distinguishing feature in the Lunar Theory is the general simplicity occasioned by the great distance of the disturbing body (the sun alone producing any sensible disturbance), in proportion to the moon's distance from the earth. The magnitude of the disturbing body renders these disturbances very much more conspicuous than any others in the solar system; and, on this account, as well as for the accuracy with which they can be observed, these disturbances have, **since the invention of the Theory of Gravitation, been considered the best tests of the truth of the theory.**

Some of the disturbances are independent of the excentricity of the **moon's orbit; others depend, in a very remarkable manner, upon the excentricity. We shall commence with the former.**

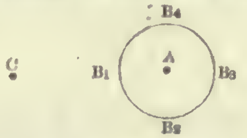
(88.) The general nature of the disturbing force on the moon may be thus stated. (See (77) to (86).) When the moon is either at the point between the earth and sun, or at that opposite to the sun (both which points are called syzygies), the force is entirely in the direction of the radius vector, and directed from the earth. When the moon is (very nearly) in the situations at which the radius vector is perpendicular to the line joining the earth and sun (both which points are called quadratures), the force is entirely in the direction of the radius vector, and directed to the earth. At certain intermediate points there is no disturbing force in the direction of the radius vector. Except at syzygies and quadratures, there is always a force perpendicular to the radius vector, such as to retard the moon while she goes from syzygy to quadrature, and to accelerate her while she goes from quadrature to **syzygy.**

(89.) I. As the disturbing force, in the direction of the radius vector directed from the earth, is greater than that directed to the earth, we may consider that, upon the whole, the effect of the disturbing force is to diminish the earth's attraction. Thus the moon's mean distance from the earth is less (see (46)) than it would have been with the same periodic time, if the sun had not disturbed it. The force perpendicular to the radius vector sometimes accelerates the moon, and sometimes retards it, and, therefore, produces no **permanent effect.**

(90.) II. But the sun's distance from the earth is subject to alteration, because the earth revolves in an elliptic orbit round the sun. Now, we have seen (83) that the magnitude of the disturbing force is inversely proportional to the cube of the sun's distance; and, consequently, it is sensibly greater when the earth is at perihelion than when at aphelion. Therefore, while the earth moves from perihelion to aphelion, the disturbing force is continually diminishing; and while it moves from aphelion to perihelion, the disturbing force is constantly increasing. Referring then to (47) it will be seen, that in the former of these times the moon's orbit is gradually diminishing, and that in the latter it is gradually enlarging. And though this alteration is not great (the whole variation of dimensions, from greatest to least, being less than $\frac{1}{5000}$, the effect on the angular **motion (see (49)) is very considerable; the anguar velocity** becoming quicker in the former time and slower in the latter; so that while the earth moves from perihelion to aphelion, the moon's angular motion is constantly becoming quicker, and while the earth **moves from aphelion to perihelion the moon's angular motion is constantly becoming slower. Now, if the moon's mean motion is determined by comparing two places observed at the interval of many years, the angular motion so found is a mean between the greatest and least. Therefore, when the earth is at perihelion, the moon's angular motion is slower than its mean motion; and when the earth is at aphelion, the moon's angular motion is quicker than its mean motion.** Consequently, **while the earth is going from perihelion to aphelion, the moon's true place is always behind its** mean place (as during the first half of that period the moon's true place is dropping behind the mean place, and during the latter half is gaining again the quantity which it had dropped behind); and while the earth is going from aphelion to perihelion, the moon's true place is always before its mean place. This inequality is called the moon's *annual equation*; it was discovered by Tycho Brahé from observation, about 1590; and its greatest value is about 10′, by which the true place is sometimes before and sometimes **behind the mean place.**

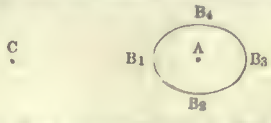
(91.) III. The disturbances which are periodical in every revolution of the moon, and are independent of excentricity, may thus be investigated. Suppose the sun to stand still for a few revolutions of the moon (or rather suppose the earth to be stationary), and let us inquire in what kind of orbit, symmetrical on opposite sides, the sun can move. It cannot move in a circle: for the force perpendicular to the radius vector retards the moon as it goes from B_1 to B_2, *fig.* 24,

Fig. 24.



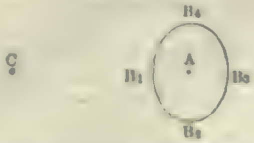
and its velocity is therefore less at B_2 than at B_1, and on this account (supposing the force directed to A at B_2 equal to the force directed to A at B_1), the orbit would be more curved at B_2 than at B_1. But the force directed to A at B_2 is much greater than at B_1 (see (88)); and on this account the orbit would be still more curved at B_2 than at B_1; whereas, in a circle, the curvature is everywhere the same. The orbit cannot therefore be circular. Neither can it be an oval with the earth in its centre, and with its longer axis passing through the sun, as *fig.* 25; for the velocity being small at B_2 (in consequence

Fig. 25.



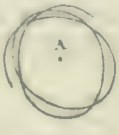
of the disturbing force perpendicular to the radius vector having retarded it) while the earth's attraction is great (in consequence of the nearness of B_2), and increased by the disturbing force in the radius vector directed towards the earth, the curvature at B_2 ought to be much greater than at B_1, where the velocity is great, the moon far off, and the disturbing force directed from the earth. But, on the contrary, the curvature at B_2 is much less than at B_1; therefore, this form of orbit is not the true one. But if the orbit be supposed to be oval, with its shorter axis directed towards the sun, as in *fig.* 26, all the conditions will be satisfied. For the velocity at B_2 is diminished by the disturbing force having acted perpendicularly to the radius vector, while the moon goes from B_1 to B_2; and though, the distance from A being greater, the earth's attraction at B_2 will be less than the attraction at B_1; yet, when increased by the disturbing force, directed to A at B_2, it will be very little less than the attraction diminished by the disturbing force at B_1. The diminution of velocity then at B_2 being considerable, and the diminution of force small, the curvature will be increased; and this increase of curvature, by proper choice of the proportions of the oval, may be precisely such as corresponds to the real difference of curvature in the different parts of the oval. Hence, such an oval may be described by the moon without alteration in successive revolutions.

Fig. 26.



(92.) We have here supposed the earth to be stationary with respect to the sun. If however we take the true case of the earth moving round the sun, or the sun appearing to move round the earth, we have only to suppose that the oval twists round after the sun, and the same reasoning applies. The curve described by the moon is then such as is represented in *fig.* 27. As the disturbing force, perpendicular to the radius vector, acts in the same direction for a longer time than in the former case, the difference in the velocity at syzygies and at quadratures is greater than in the former case, and this will require the oval to differ from a circle, rather more than if the sun be supposed to stand still.

Fig. 27.



(93.) If, now, in such an orbit as we have mentioned, the law of *uniform description of areas by the radius vector* were followed, as it would be if there were no force perpendicular to the radius vector, the angular motion of the moon near B_2 and B_4, *fig.* 26, would be much less than that near B_1 and B_3. But in consequence of the disturbing force, perpendicular to the radius vector (which retards the moon from B_1 to B_2, and from B_3 to B_4, and accelerates it from B_2 to B_3, and from B_4 to B_1), the angular motion is still less at B_2 and B_4, and still greater at B_1 and B_3. The angular motion therefore diminishes considerably while the moon moves from B_1 to B_2, and increases considerably while it moves from B_2 to B_3, &c. The mean angular motion, determined by observation, is less than the former and greater than the latter. Consequently, the angular motion at B_1 is greater than the mean, and that at B_2 is less than the mean; and therefore (as in (90),) from B_1 to B_2 the moon's true place is before the mean; from B_2 to B_3 the true place is behind the mean; from B_3 to B_4 the true place is before the mean; and from B_4 to B_1 the true place is behind the mean. This inequality is called the moon's *variation*; it amounts to about 32′, by which the moon's true place is sometimes before and sometimes behind the mean place. It was discovered by Tycho Brahé, from observation about 1590.

(94.) We have however mentioned, in (79), that the disturbing forces are not exactly equal on the side of the orbit which is next the sun, and on that which is farthest from the sun; the former being rather greater. To take account of the effects of this difference, let us suppose, that in the investigation just finished, we use a mean value of the disturbing force. Then we must, to represent the real case, suppose the disturbing force near conjunction to be increased, and that near opposition to be diminished. Observing what the nature of these forces is (77), (78), and (84), this amounts to supposing that near conjunction the force necessary to make up the difference is a force acting in the radius vector, and directed from the earth, and a force perpendicular to the radius vector, accelerating the moon before conjunction, and retarding her after it, and that near opposition the forces are exactly of the contrary kind. Let us then lay aside the consideration of all other disturbing forces, and consider the inequality which these forces alone will produce. As they are very small, they will not in one revolution alter the orbit sensibly from an elliptic form. What then must be the excentricity, and what the position of the line of apses that, with these disturbing forces only, the same kind of orbit may always be described? A very little consideration of (57), (58), and (68), will show, that unless the line of apses pass through the sun, the excentricity will either be increasing or diminishing from the action of these forces. We must assume therefore, as our orbit is to have the same excentricity at each revolution, that the line of apses passes through the sun. But is the perigee or the apogee to be turned towards the sun? To answer this question we have only to observe that the lines of apses must progress as fast as the sun appears to progress, and we must therefore choose that position in which the forces will cause progression of the line of apses. If the perigee be directed to the sun, then the forces at both parts of the orbit will, by (51), (54), (65), and (66), cause the line of apses to regress. This supposition, then, cannot be admitted. But if the apogee be directed to the sun, the forces at both parts of the orbit will cause it to progress; and by (56), if a proper value is given to the excentricity it will progress exactly as fast as the sun appears to progress. The effect, then, of the difference of forces of which we have spoken, is to elongate the orbit towards the sun, and to compress it on the opposite side. This irregularity is called the *parallactic inequality*.

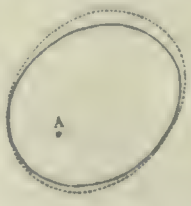
We shall shortly show, that if the moon revolved in such an elliptic orbit as we have mentioned, the effect of the other disturbing forces (independent of that discussed here) would be to make its line of apses progress with a considerable velocity. The force considered here, therefore, will merely have to cause a progression which, added to that just mentioned, will equal the sun's apparent motion round the earth. The excentricity of the ellipse, in which it could produce this smaller motion, will (56) be greater than that of the ellipse in which the same force could produce the whole motion. Thus the magnitude of the parallactic inequality is considerably increased by the indirect effect of the other disturbing forces.

(95.) The magnitude of the forces concerned here is about $\frac{1}{130}$th of those concerned in (91), &c.; but the effect is about $\frac{1}{11}$th of their effect. This is a striking instance of the difference of proportions, in forces and the effects that they produce, depending on the difference in their modes of action. The inequality here discussed is a very interesting one, from the circumstance that it enables us to determine with considerable accuracy the proportion of the sun's distance to the moon's distance, which none of the others will do, as it is found upon calculation that their magnitude depends upon nothing but the excentricities and the proportion of the periodic times, all which are known without knowing the proportion of distances.

(96.) The effect of this, it will be readily understood, is to be combined with that already found. [See the Note to (134).] The moon's orbit therefore is more flattened on the side farthest from the sun, and less flattened on the side next the sun, than we found in (91) and (92). The equable description of areas is scarcely affected by these forces. The moon's *variation* therefore is somewhat diminished near conjunction, and is somewhat increased near opposition.

(97.) It will easily be imagined, that if there is an excentricity in the moon's orbit, the effect of the *variation* upon that orbit will be almost exactly the same as if there were no excentricity.* Thus, supposing that the orbit without the disturbing force had such a form as the dark line in *fig.* 28, it will, with the disturbing force, have such a form as the dotted line in that figure. The same must be understood in many other cases of different inequalities which affect the motion of the same body.

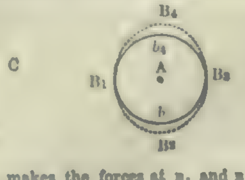
Fig. 28.



---

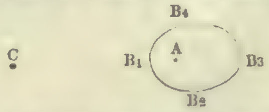
* As this general proposition is of considerable importance, we shall point out the nature of the reasoning by which (with proper alteration for different cases), the reader may satisfy himself of its correctness. The reason why, in *fig.* 29, the moon cannot describe the circle B_1, b_2, B_3, b_4, though it touches at B_1 and B_3, and the reason that it will describe the oval B_1, B_2, B_3, B , is, that the disturbing force makes the forces at B_1 and B_3 less than they would otherwise have been, and greater at B_2 and B_4 than they would otherwise have been; and the velocity is, by that part of the force perpendicular to the radius vector, made less at B_2 than it would otherwise have been. So that, unless we supposed it moving at B_1 with a greater velocity than it would have had undisturbed in the circle B_1, b_2, B_3, b_4, the great curvature produced by the great force and diminished velocity at B_2 would have brought it much nearer to A than the point B_2; but with this large velocity at B_1, it will go out further at B_4, and then the great curvature may make it pass exactly through B_3. In like manner, in *fig.* 30, if the velocity at B_1 were not greater than it would have had undisturbed in the ellipse B_1, b_2, B_3, b_4, the increased curvature at B_2, produced by the increased force and diminished velocity there, would have brought it much nearer to A than the point B_2; but with a large velocity at B_1 it will go out at B_2 further than it would otherwise have gone out, and then the increased force and diminished velocity will curve its course so much, that it may touch the elliptic orbit at B_3; and so on. The whole explanation, in

Fig. 29.



(98.) IV. We now proceed with the disturbances dependent on the excentricity: and first with the motion of the moon's perigee. In the first place, suppose that the perigee is on the same side as the sun. While the moon is near B_1, *fig.* 31, that is, near perigee, the

Fig. 31.



disturbing force is directed from A; and consequently by (51) the line of apses regresses. While the moon is near B_3, that is, near apogee, the disturbing force is also directed from A, and consequently by (54) the line of apses progresses. The question then now is, which is the greater, the regress, when the moon is near B_1, or the progress, when it is near B_3? To answer this we will remark, that if the disturbing force directed from A were inversely proportional to the square of the distance (and consequently less at B_3 than at B_1), it would amount to exactly the same as if the attraction of A were altered in a given proportion;[*] and in that case B would describe round A an ellipse, whose line of apses was invariable; or the progression produced at B_3 would be equal to the regression produced at B_1. But in fact the disturbing force at B_3 is to that at B_1 in the same proportion as A B_3 to A B_1, by (32); and therefore the disturbing force at B_3 is greater than that at B_1, and consequently much greater than that which would produce a progression equal to the regression produced at B_1; and therefore the effects of the disturbing force at B_3 predominate, and the line of apses progresses. The disturbing force directed to A in the neighbourhood of B_2 and B_4 scarcely produces any effect, as on one side of each of those points the effect is of one kind, and on the other side it is of the opposite kind (55).

(99.) The disturbing force directed from A, though the only one at B_1 and B_3, is not however the only one in the neighbourhood of B_1 and B_3. While the moon is approaching to B_1, the force perpendicular to the radius vector accelerates the moon, and therefore, by (65), as B_1 is the place of perigee, the line of apses regresses: when the moon has passed B_1 the force retards the moon, and therefore, by (66), the line of apses still regresses. But when the moon is approaching B_3, the force perpendicular to the radius vector accelerates the moon; and therefore, by (65) and (66), as B_3 is the place of apogee, the line of apses progresses; when the moon has passed B_3, the force retards the moon, and the line of apses still progresses. The question now is, whether the progression produced by the force perpendicular to the radius vector near B_3 will or will not exceed the regression produced near B_1? To answer this we must observe, that the rate of this progress or regress depends entirely upon the proportion[†] which the velocity produced by the disturbing force bears to the velocity of the moon; and since from B_2 to B_3, and from B_3 to B_4, the disturbing force is greater than that from B_4 to B_1, and from B_1 to B_2, and acts for a longer time (as by the law of equable description of areas, the moon is longer moving from B_2 to B_3 and B_4 than from B_4 to B_1 and B_2), and since the moon's velocity in passing through B_2, B_3, B_4, is less than her velocity in passing through B_4, B_1, B_2, it follows that the effect in passing through B_2, B_3, B_4, is much greater than that in passing through B_4, B_1, and B_2. Consequently, the effect of this force also is to make the line of apses progress.

(100.) On the whole, therefore, when the perigee is turned towards the sun, the line of apses progresses rapidly: And the same reasoning applies in every respect when the perigee is turned from the sun.

(101.) In the second place, suppose that the line of apses is perpendicular to the line joining the earth and sun. The disturbing force at both apses is now directed to the earth, and consequently by (50) and (53), while the moon is near perigee, the disturbing force causes the line of apses to progress, and while the moon is near apogee the disturbing force causes the line of apses to regress. Here, as in the last article, the effects at perigee and at apogee would balance if the disturbing force were inversely proportional to the square of the distance from the earth. But the disturbing force is really proportional to the distance from the earth; and therefore, as in (98), the effect of the disturbing force, while the moon is at apogee, preponderates over the other; and therefore the force directed to the centre causes the line of apses to regress.

(102.) We must also consider the force perpendicular to the radius vector. In this instance that force retards the moon while she is approaching to each apse, and accelerates her as she recedes from it. The effect is, that when the moon is near perigee the force causes the line of apses to progress, and when near apogee it causes the line of apses to regress (65) and (66). The latter is found to preponderate, by the same reasoning as that in (99). From the effect, then, of both causes, the line of apses regresses rapidly in this position of the line of apses.

(103.) It is important to observe here, that the motion of the line of apses would not, as in (56), be greater if the excentricity of the orbit were smaller; for, though the motion of the line of apses is greater *in proportion to the force which causes it* when the excentricity is smaller, yet, in the present instance, the force which causes it is itself proportional to the excentricity (inasmuch as it is the difference of the forces at perigee and apogee, which would be equal if there were no excentricity): so that if the excentricity were made less, the force which causes the motion of the line of apses would also be made less, and the motion of the line of apses would be nearly the same as before.

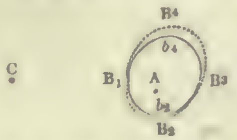
(104.) It appears, then, that when the line of apses passes through the sun, the disturbing force causes that line to progress; when the earth has moved round the sun, or the sun has appeared to move round the earth, so far that the line of apses is perpendicular to the line joining the sun and the earth, the line of apses regresses from the effect of the disturbing force; and at some intermediate position it may easily be imagined that the force produces no effect on it. It becomes now a matter of great interest to inquire, whether, upon the whole, the progression exceeds the regression. Now, the force perpendicular to the radius vector, considered in (99), is almost exactly equal to that considered in (102); so that the progression produced by that force when the line of apses passes through the sun, is almost exactly equal to the regression which it produces when the line of apses is perpendicular to the line joining the earth and sun; and this force may therefore be considered as producing no effect (except indirectly, as will be hereafter mentioned). But the force in the direction of the radius vector, tending from the earth in (98), is, as we have mentioned in (80), almost exactly double of that tending to the earth in (101), and therefore its effect predominates; and therefore, on the whole, the line of apses progresses. In fact, the progress, when the line of apses passes through the sun, is about 11° in each revolution of the moon; the regress, when the line of apses is perpendicular to the line joining the earth and sun, is about 9° in each revolution of the moon.

(105.) The progression of the line of apses of the moon is considerably

---

one case as much as in the other, depends entirely upon the difference of the forces in the actual case, from the forces, if the moon were not disturbed.

Fig. 30.



[*] The reasoning in the text may be more fully stated thus: If, with the original attractive force of the earth there be combined another force, directed from the earth, and always bearing the same proportion to the earth's original attraction, this combined force may be considered in two ways: 1st, As a smaller attraction, always proportional to the original attraction, or inversely proportional to the square of the distance. 2nd, As the original attraction, with a force superadded, which may be treated as a disturbing force. The result of the first mode of consideration will be, that the moon will describe an ellipse, whose line of apses does not move. The result of the second mode of consideration will be, that the instantaneous ellipse (in which the moon would proceed to move, if the additional force should cease) will have its line of apses regressing, while the moon is near perigee, and progressing while she is near apogee. There is however no incongruity between the immobility of the line of apses in the first mode of consideration, and the progress or regress in the second; because the line of apses of the instantaneous ellipse in the second case is an imaginary line, determined by supposing the disturbing force to cease, and the moon to move undisturbed. At the apses however the line of apses must be the same in both methods of consideration; since, whether the disturbing force cease or not, the perpendicularity of the direction of the motion to the radius vector determines the place of an apse. Consequently, while the moon moves from one apse to the other, the motions of the line of apses in the second mode of consideration must be such as to produce the same effect on the position of the line of apses as in the first mode of consideration; that is, they must not have altered its place; and hence the progression at one time must be exactly equal to the regression at the other time.

[†] Suppose, for facility of conception, that the force perpendicular to the radius vector acts in only one place in each quadrant between syzygies and quadratures. The portions of the orbit which are bisected by the line of syzygies will be described with greater velocity in consequence of this disturbance (abstracting all other causes), than the other portions. Now the curvature of any part of an orbit does not depend on the central force simply, or on the velocity, but on the relation between them; so that the same curve may be described either by leaving the central force unaltered and increasing the velocity in a given proportion, or by diminishing the central force in a corresponding proportion, and leaving the velocity unaltered. Consequently, in the case before us, the same curve will be described as if, without alteration of velocity, the central force were diminished, while the moon passed through the portions bisected by the line of syzygies. If now the imaginary diminution of central force were in the same proportion (that is, if the real increase of velocity were in the same proportion) at both syzygies, which here coincide with the apses, the regression of the line of apses produced at perigee would be equal to the progression produced at apogee. But the increase of velocity produced by the force perpendicular to the radius vector near apogee is much greater than that near perigee. First, because the force is greater in proportion to the distance. Second, because the time of describing a given small angle is greater in proportion to the square of the distance; so that the acceleration produced while the moon passes through a given angle is proportional to the cube of the distance. Third, because the velocity, which is increased by this acceleration, is inversely proportional to the distance; so that the ratio in which the velocity is increased is proportional to the fourth power of the distance. The effect at the greater distance therefore predominates over that at the smaller distance; and therefore, on the whole, the force perpendicular to the radius vector produces an effect similar to its apogeal effect; that is, it causes the line of apses to progress.

greater than the first consideration would lead us to think, for the following reasons :—

(106.) Firstly. The earth is revolving round the sun, or the sun appears to move round the earth, in the same direction in which the moon is going. This lengthens the time for which the sun acts in any one manner upon the moon, but it lengthens it more for the time in which the moon is moving slowly, than for that in which it is moving quickly. Thus, suppose that the moon's angular motion when she is near perigee is fourteen times the sun's angular motion ; and when near apogee, only ten times the sun's motion. Then she passes the sun at the former time (as seen from the earth), with $\frac{13}{14}$ths of her whole motion, but at the latter with only $\frac{9}{10}$ths ; consequently, when near perigee, the time in which the moon passes through a given angle from the moving line of syzygies (or the time in which the angle between the sun and moon increases by a given quantity), is $\frac{14}{13}$ths of the time in which it would have passed through the same angle, had the sun been stationary ; when near apogee, the number expressing the proportion is $\frac{10}{9}$ths. The latter number is greater than the former ; and, therefore, the effect of the forces acting near apogee is increased in a greater proportion than that of the forces acting near perigee. And as the effective motion of the line of apses is produced by the excess of the apogeal effect above the perigeal effect, a very small addition to the former will bear a considerable proportion to the effective motion previously found ; and thus the effective motion will be sensibly increased.

(107.) Secondly. When the line of apses is directed toward the sun, the whole effect of the force is to make it progress,—that is, to move in the same direction as the sun : the sun passes through about 27° in one revolution of the moon, and therefore departs only 16° from the line of apses ; and therefore the apse continues a long time near the sun. When at right angles to the line joining the earth and sun, the whole effect of the force is to make it regress ; and, therefore, moving in the direction opposite to the sun's motion, the angle between the sun and the line of apses is increased by 36° in each revolution, and the line of apses soon escapes from this position. The effect of the former force is therefore increased, while that of the latter is diminished ; and the preponderance of the former is much increased. It is in increasing the rapidity of progress at one time, and the rapidity of regress at another, that the force perpendicular to the radius vector indirectly increases the effect of the former in the manner just described.

(108.) From the combined effect of these two causes, the actual progression of the line of apses is nearly double of what it would have been if, in different revolutions of the moon, different parts of its orbit had been equally subjected to the disturbing force of the sun.

(109.) The line of apses, upon the whole, therefore, progresses ; and (as calculation and observation agree in showing) with an angular velocity that makes it (on the average) describe 3° in each revolution of the moon, and that carries it completely round in nearly nine years. But as it sometimes progresses and sometimes regresses for several months together, its motion its extremely irregular. The general motion of the line of apses has been known from the earliest ages of astronomy.

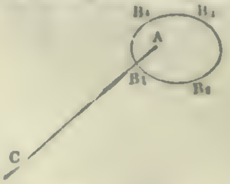
(110.) V. For the alteration of the excentricity of the moon's orbit : first, let us consider the orbit in the position in which the line of apses passes through the sun, *fig.* 31. While the moon moves from B_1 (the perigee) to B_3 (the apogee), the force in the direction of the radius vector is sometimes directed to the earth, and sometimes from the earth ; and, therefore, by (57) and (59), it sometimes diminishes the excentricity and sometimes increases it. But while the moon moves from B_3 to B_1, there are exactly equal forces acting in the same manner at corresponding parts of the half-orbit, and these, by (58), will produce effects exactly opposite. On the whole, therefore, the disturbing force in the direction of the radius vector produces no effect on the excentricity. The force perpendicular to the radius vector increases the moon's velocity when moving from B_4 to B_1, and diminishes it when moving from B_1 to B_2; in moving, therefore, from B_4 to B_1, the excentricity is increased (65) ; and in moving from B_1 to B_2, it is as much diminished (66). Similarly, in moving from B_2 to B_3, the excentricity is diminished ; and in moving from B_3 to B_4, it is as much increased. This force, therefore, produces no effect on the excentricity.

On the whole, therefore, while the line of apses passes through the sun, the disturbing forces produce no effect on the excentricity of the moon's orbit.

(111.) When the line of apses is perpendicular to the line joining the earth and sun, the same thing is true. Though the forces near perigee and near apogee are not now the same as in the last case, their effects on different sides of perigee and apogee balance each other in the same way.

(112.) But if the line of apses is inclined to the line joining the earth and sun, as in *fig.* 32, the effects of the forces do not balance. While the moon is near B_4 and near B_2 the disturbing force in the radius vector is directed to the earth ; at B_4 therefore, (58), as the moon is moving towards perigee, the excentricity is increased ; and at B_2, as the moon is moving from perigee, the excentricity is diminished. From the slowness of the motion at B_2 (which gives the disturbing force more time to produce its effects), and the greatness of the force, the effect at B_2 will preponderate, and the combined effects at B_2 and B_4 will diminish the excentricity. This will appear from reasoning of the same kind as that in (98). At B_1 and B_3 the force in the radius vector is directed from the earth : at B_1, therefore, by (59), as the moon is moving from perigee, the excentricity is increased, and at B_3 it is diminished ; but from the slowness of the motion at B_3 and the magnitude of the force, the effect at B_3 will preponderate, and the combined effects at B_1 and B_3 will diminish the excentricity. On the whole, therefore, the force in the direction of the radius vector diminishes the excentricity. The force perpendicular to the radius vector retards the moon from B_1 to B_2, but the first part of this motion may be considered near perigee, and the second near apogee, and, therefore, in the first part, it diminishes the excentricity, and in the second increases it ; and the whole effect from B_1 to B_2 is very small. Similarly, the whole effect from B_3 to B_4 is very small. But from B_4 to B_1 the force accelerates the moon, and, therefore, by (68), (the moon being near perigee) increases the excentricity ; and from B_2 to B_3 the force also accelerates the moon, and by (68) (the moon being near apogee) diminishes the excentricity ; and the effect is much * greater (from the slowness of the moon and the greatness of the force) between B_2 and B_3, than between B_4 and B_1, and therefore the combined effect of the forces in these two quadrants is to diminish the excentricity.

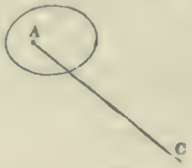
Fig. 32.



On the whole, therefore, when the line of apses is inclined to the line joining the earth and sun, in such manner that the moon passes the line of apses before passing the line joining the earth and sun, the excentricity is diminished at every revolution of the moon.

(113.) In the same manner it will appear that if the line of apses is so inclined that the moon passes the line of apses after passing the line joining the earth and sun, the excentricity is increased at every revolution of the moon. Here the force in the radius vector is directed to the earth, as the moon moves from perigee and from apogee ; and is directed from the earth as the moon moves to perigee and to apogee ; which directions are just opposite to those in the case already considered. Also the force perpendicular to the radius vector retards the moon both near perigee and near apogee ; and this is opposite to the direction in the case already considered. On the whole, therefore, the excentricity is increased at every revolution of the moon.

Fig. 33.



(114.) In every one of these cases the effect is exactly the same if the sun be supposed on the side of the moon's orbit, opposite to that represented in the figure.

---

* To the reader who is acquainted with Newton's 3rd section, the following demonstration of this point will be sufficient : Four times the reciprocal of the *latus rectum* is equal to the sum of the reciprocals of the apogeal and perigeal distances. The effect of an increase of velocity at perigee in a given proportion is to alter the area described in a given time in the same proportion, and therefore to alter the *latus rectum* in a corresponding proportion. Consequently an increase of velocity at perigee in a given proportion alters the reciprocal of the apogeal distance by a given quantity, and therefore alters the apogeal distance by a quantity nearly proportional to the square of the apogeal distance ; and therefore the ratio of the alteration of apogeal distance to apogeal distance (on which the alteration of excentricity depends) is nearly proportional to the apogeal distance. Similarly, if the velocity at apogee is increased in a given proportion, the ratio of the alteration of perigeal distance to perigeal distance (on which the alteration of excentricity depends) is nearly proportional to the perigeal distance. Thus if the velocity were increased in the same proportion at perigee and at apogee, the increase of excentricity at the former would be greater than the diminution at the latter, in the proportion of apogeal distance to perigeal distance. But in the case before us, the proportion of increase of velocity is much greater at apogee than at perigee. First, because the force is greater (being in the same proportion as the distance). Second, because the time in which the moon describes a given angle is greater (being in the same proportion as the square of the distance), so that the increase of velocity is in the proportion of the cube of the distance. Third, because the actual velocity is less (being inversely as the distance), so that the ratio of the increase to the actual velocity is proportional to the fourth power of the distance. Combining this proportion with that above, the alterations of excentricity in the case before us, produced by the forces acting at apogee and at perigee, are in the proportion of the cubes of the apogeal and perigeal distances respectively.

(115.) Now the earth moves round the sun, and the sun therefore appears to move round the earth, in the order successively represented by the *figs.* 31, 32, and 33. Hence; then; when the sun is in the line of the moon's apses, the excentricity does not alter (110); after this it diminishes till the sun is seen at right angles to the line of apses (112); then it does not alter (111); and after this it increases till the sun reaches the line of apses on the other side. Consequently, the excentricity is greatest when the line of apses passes through the sun, and is least when the line of apses is perpendicular to the line joining the earth and sun.

The amount of this alteration in the excentricity of the moon's orbit is more than $\frac{1}{5}$th of the mean value of the excentricity; the excentricity being sometimes increased by this part, and sometimes as much diminished; so that the greatest and least excentricities are nearly in the proportion of 6 : 4 or 3 : 2.

(116.) The principal inequalities in the moon's motion may therefore be stated thus:

1st. The *elliptic inequality*, or *equation of the centre* (31), which would exist if it were not disturbed.
2nd. The *annual equation* (90), depending on the position of the earth in the earth's orbit.
3rd. The *variation* (93), and *parallactic inequality* (94), depending on the position of the moon with respect to the sun.
4th. The general *progression of the moon's perigee* (104).
5th. The *irregularity in the motion of the perigee*, depending on the position of the perigee with respect to the sun (109).
6th. The *alternate increase and diminution of the excentricity*, depending on the position of the perigee with respect to the sun (115).

These inequalities were first explained (some imperfectly) by Newton, about 1680.

(117.) The effects of the two last are combined into one called the *evection*. This is by far the largest of the inequalities affecting the moon's place: the moon's longitude is sometimes increased 1° 15′ and sometimes diminished as much by this inequality. It was discovered by Ptolemy, from observation, about A.D. 140.

(118.) It will easily be imagined that we have here taken only the principal inequalities. There are many others, arising chiefly from small errors in the suppositions that we have made. Some of these, it may easily be seen, will arise from variations of force which we have already explained. Thus the difference of disturbing forces at conjunction and at opposition, whose principal effect was discussed in (94), will also produce a sensible inequality in the rate of progression of the line of apses, and in the dimensions of the moon's orbit. The alteration of disturbing force depending on the excentricity of the earth's orbit will cause an alteration in the magnitude of the *variation* and the *evection*. The alteration of that part mentioned in (94) produces a sensible effect depending on the angle made by the moon's radius vector with the earth's line of apses. All these, however, are very small: yet not so small but that, for astronomical purposes, it is necessary to take account of thirty or forty.

(119.) There is, however, one inequality of great historical interest, affecting the moon's motion, of which we may be able to give the reader a general idea. We have stated in (89) that the effect of the disturbing force is, upon the whole, to diminish the moon's gravity to the earth: and in (90) we have mentioned that this effect is greater when the earth is near perihelion, than when the earth is near aphelion. It is found, upon accurate investigation, that half the sum of the effects at perihelion and at aphelion is greater than the effect at mean distance, by a small quantity depending on the excentricity of the earth's orbit: and, consequently, the greater the excentricity (the mean distance being unaltered) the greater is the effect of the sun's disturbing force. Now, in the lapse of ages, the earth's mean distance is not sensible altered by the disturbances which the planets produce in its motion; but the excentricity of the earth's orbit is sensibly diminished, and has been diminishing for thousands of years. Consequently the effect of the sun in disturbing the moon has been gradually diminishing, and the gravity to the earth has therefore, on the whole, been gradually increasing. The size of the moon's orbit has therefore, gradually, but insensibly, diminished (47): but the moon's place in its orbit has sensibly altered (49), and the moon's angular motion has appeared to be perpetually quickened. This phenomen was known to astronomers by the name of the *acceleration of the moon's mean motion*, before it was theoretically explained in 1787, by Laplace: on taking it into account, the oldest and the newest observations are equally well represented by theory. The rate of progress of the moon's line of apses has, from the same cause, been somewhat diminished.

SECTION VI.—*Theory of Jupiter's Satellites.*

(120.) Jupiter has four satellites revolving round him in the same manner in which the moon revolves round the earth; and it might seem, therefore, that the theory of the irregularities in the motion of these satellites is similar to the theory of the irregularities in the moon's motion. But the fact is, that they are entirely different. The fourth satellite (or that revolving in the largest orbit) has a small irregularity analogous to the moon's variation, a small one similar to the evection, and one similar to the annual equation: but the last of these amounts only to about two minutes, and the other two are very much less. The corresponding inequalities in the motion of the other satellites are still smaller. But these satellites disturb each other's motions, to an amount and in a manner of which there is no other example in the solar system; and (as we shall afterwards mention) their motions are affected in a most remarkable degree by the shape of Jupiter.

(121.) The theory, however, of these satellites is much simplified by the following circumstances:—First, the disturbances produced by the sun may, except for the most accurate computations, be wholly neglected. Secondly, that the orbits of the two inner satellites have no excentricity independent of perturbation. Thirdly, that a very remarkable relation exists (and, as we shall show, necessarily exists) between the motions of the three first satellites.

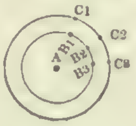
Before proceeding with the theory of the first three satellites, we shall consider a general proposition which applies to each of them.

(122.) Suppose that two small satellites revolve round the same planet; and that the periodic time of the second is a very little greater than double the periodic time of the first; what is the form of the orbit in which each can revolve, describing a curve of the same form at every revolution?

(123.) The orbits will be sensibly elliptical, as the perturbation produced by a small satellite in one revolution will not sensibly alter the form of the orbit. The same form being supposed to be described each time, the major axis and the excentricity are supposed invariable, and the position of the line of apses only is assumed to be variable. The question then becomes, What is the excentricity of each orbit, and what the variation of the position of the line of apses, in order that a curve of the same kind may be described at every revolution?

(124.) In *fig.* 34, let B_3, B_1, B_2, represent the orbit of the first, and C_3, C_1, C_2, the orbit of the second. Suppose that when B was at B_1, C was at C_1, so that A, B_1, C_1, were in the same straight line, or that B and C were in conjunction at these points. If the periodic time of C were exactly double of the periodic time of B, B would have made exactly two revolutions, while C made exactly one; and, therefore, B and C would again be in conjunction at B_1, and C_1. But as the periodic time of C is a little longer than double that of B, or the angular motion of C rather slower than is supposed, B will have come up to it (in respect of longitude as seen from A) at some line B_2 C_2, which it reaches *before* reaching the former line of conjunction B C_1. And it is plain that there has been no other conjunction since that with which we started as the successive conjunctions can take place only when one satellite has gained a whole revolution on the other. The first conjunction then being in the line A B_1 C_1, the next will be in the line A B_2 C_2, the next in a line A B_3 C_3, still farther from the first, &c.; so that the line of conjunction will regress slowly; and the more nearly the periodic time of one satellite is double that of the other, the more slowly will the line of conjunction regress.

Fig. 34.



(125.) As the principal part of the perturbation is produced when the satellites are near conjunction (in consequence of the smallness of their distance at that time), it is sufficiently clear that the position of the line of apses, as influenced by the perturbation, must depend on the position of the line of conjunction; and, therefore, that the motion of the line of apses must be the same as the motion of the line of conjunction. Our question now becomes this: What must be the excentricities of the orbits, and what the positions of the perijoves, in order that the motions of the lines of apses, produced by the perturbation, may be the same as the motion of the line of conjunction?

(126.) If the line of apses of the first satellite does not coincide with the line of conjunction, the first satellite at the time of conjunction will either be moving from perijove towards apojove, or from apojove towards perijove. If the former, the disturbing force, which is directed from the central body, will, by (59), cause the excentricity to increase; if the latter, it will cause it to decrease. As we have started with the supposition, that the excentricity is to be supposed invariable, neither of these consequences can be allowed, and, therefore, the line of apses must coincide with the line of conjunction.

(127.) If the apojove of the first satellite were in the direction of the points of conjunction, the disturbing force in the direction of the radius vector, being directed from the central body, would, by (54), cause the line of apses to progress. Also the force perpendicular to the radius vector, before the first satellite has reached conjunction (and when the second satellite, which moves more slowly, is nearer to the point of conjunction than the first), tends to accelerate the first satellite; and that which acts after the satellites have passed conjunction, tends to retard the first satellite; and both these, by (65) and (66), cause the line of apses to progress. But we have assumed, that the line of apses shall move in the same direction as the line of conjunction, that is, shall regress; therefore, the apojove of the first satellite cannot be in the direction of the points of conjunction.

(128.) But if we suppose the perijove of the first satellite to be in the direction of the points of conjunction, every thing becomes consistent. The disturbing force, in the direction of the radius vector, from the central body, will, by (51), cause the line of apses to regress. The force perpendicular to the radius vector, which accelerates the first satellite before it has reached conjunction, that is, before it has reached the perijove, and retards it after that time, will also, by (65) and (66), cause the line of apses to regress. Also, as in (56), this regression will be greater as the excentricity of the orbit is less, because the disturbing force, which acts here, does not depend on the excentricity. By proper choice, therefore, of a value of the excentricity, we can make an orbit, whose line of apses will always regress exactly as fast as the line of conjunction, and will, therefore, always coincide with it; whose excentricity, in consequence, will never alter, by (59) and (68); and whose general shape, therefore, will be the same at every successive revolution.

(129.) We shall mention hereafter, that the form of Jupiter is such as would cause the perijove of the first satellite, if it were not disturbed by the second satellite, to progress with a velocity not depending upon the excentricity of the orbit. The only alteration which this makes in our conclusions is, that the excentricity of the orbit must be so chosen, that the perturbation of which we have spoken will cause a regression equal to the *sum* of the progression which Jupiter's shape would occasion, and the regression of the line of conjunction. As this is greater than the regression of the line of conjunction alone, the excentricity of the orbit must be less. So that the only effect of Jupiter's shape is to diminish, in some degree, the excentricity of the orbit.

(130.) Now let us inquire what must be the form and position of the orbit of the second satellite. As before, the principal part of the perturbation is near conjunction. At and near the conjunction, the disturbing force, in the direction of the radius vector, is directed to the central body. Before conjunction, when the first satellite is less advanced than the second, the disturbing force, perpendicular to the radius vector, retards the second, by (86). For, the periodic time of the second being nearly double that of the first, the mean distances from the planet will be nearly in the proportion of 7 to 11 (as the proportion of the cube of 7 to the cube of 11 is nearly the same as the proportion of the square of 1 to the square of 2, see (34)), and, therefore, near conjunction, the distance of the first from the second is less than the distance of the first from the central body. After conjunction, the disturbing force accelerates the second body. Now, without going through several cases as before, which the reader will find no trouble in doing for himself, we shall remark, at once, that if the apojove of the second satellite is in the direction of the points of conjunction, both the disturbing force, directed to the central body at apojove, and that perpendicular to the radius vector, retarding it before it reaches apojove, and accelerating it afterwards, by (53), (65), and (66), will cause the line of apses to regress; and that, by proper choice of excentricity, the regression of the line of apses may be made exactly equal to the regression of the line of conjunction.

(131.) Our conclusion, therefore, is: If two satellites revolve round a primary, and if the periodic time of one is very little greater than double the periodic time of the other, and if we assume that the orbits described have always the same form; (that is, if they have no excentricity independent of perturbation); then the orbits will not sensibly differ from ellipses, the lines of apses of both orbits must always coincide with the line of conjunctions, and the perijove of the first orbit, and the apojove of the second, must always be turned towards the points of conjunction. It appears also, that these conditions are sufficient, inasmuch as the rate of regress of the lines of apses will (with proper values for the excentricities) be the same as the rate of regress of the line of conjunctions, and the excentricities then will not change. The excentricities of the orbits will be greater as the regress of the line of conjunctions is slower, or as the proportion of the periodic times approaches more exactly to the proportion of 1 : 2.

(132.) In the same manner it would be found, that if the periodic time of one satellite were very little less than double that of the other, the lines of apses (in order that similar orbits may be traced out at each revolution) must always coincide with the line of conjunction, and the apojove of the first satellite and the perijove of the second must always be turned towards the points of conjunction; and the excentricities of the orbits must be greater, as the proportion of the periodic times approaches more exactly to the proportion of 1 : 2.

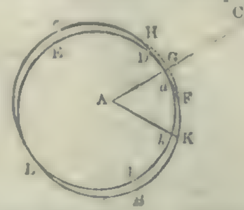
(133.) The same thing exactly would hold, if the periodic times were very nearly in the ratio of 2 : 3, or of 3 : 4, &c., but these suppositions do not apply to Jupiter's satellites.

(134.) Having thus found the distortion produced by the disturbing force in orbits which have no excentricity independent of perturbation, it will easily be imagined that the same kind of distortion will be produced if the orbits have an original excentricitiy. If we make in an elliptic orbit, the same kind of alteration which must be made in a circular orbit, in order to form the figure found above, we shall have nearly the orbit that will be described from the combined effects of perturbation and of excentricity independent of perturbation.*

---

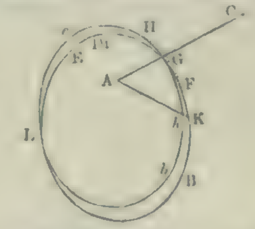
* The truth of this proposition may be shown more fully in the following manner: Let A (*fig.* 35) be the place of the primary, AC the line of conjunctions of the first and second satellite, BDE the elliptic orbit, in which the first satellite would move if undisturbed, D its perijove. Suppose (to simplify the figure) that the attraction of the second satellite acts only for a limited space; for instance, while the first satellite passes from F to H. Then the result of the investigations from (122) to (131) is, that the first satellite will be drawn

Fig. 35.



outwards from the orbit in which it would have moved, so as to describe a curve FGH; and when the disturbing force ceases at H, it will proceed to describe an ellipse, H*ebd*, similar to BDE, but with this difference, that the perijove is at *d* instead of D. The conclusion, however, now that it has been securely obtained from the reasoning above, may be stated as the result of the following reasoning: In consequence of the disturbing force, which has drawn the first satellite outwards, without, upon the whole, altering its velocity accelerating it before conjunction, and retarding it afterwards, the satellite has moved in a curve, FGH, external to the ellipse FD, in which it would have moved; and after the disturbing force has ceased at H, the satellite (which is moving in a path inclined externally from the old orbit) continues to recede from the old orbit till the diminution of velocity (26) allows its path to be so much curved, that at *e* it begins to approach, and at L the new orbit intersects the old one; and after this, the path is inclined internally from the old orbit, till the increase of velocity (25) makes its path so little curved that it approaches the old orbit again, and again crosses it between *d* and D. In like manner, if, as in *fig.* 36, the orbit BFE have an excentricity independent of perturbation (the perijove being at any point D_1), nevertheless, we may state that, in consequence of the disturbing force, the satellite will move in a curve FGH external to FE; but when the disturbing force ceases at H, the satellite (which is moving in a path

Fig. 36.



inclined externally from the old orbit) continues to recede from the old orbit till the diminution of velocity (26) allows its path to be so much curved, that it begins to approach at some point *e*; that at some point L, nearly opposite to C, the new orbit intersects the old one; and that, after this, the path is inclined internally from the old orbit, till the increase of velocity (25) makes its path so little curved that it approaches the old orbit again, and again crosses it between F and H. Thus, the alteration of the radius vector, drawn in any given direction, as AK (which in the new orbit is altered to A*k*) is nearly the same in the second case as in the first. This, however, is the alteration produced in a single revolution of the satellite; but as the same applies to every successive revolution, it follows that the inequality or variation of the radius vector in the second case is nearly the same as in the first case; and thus the proposition of the text is proved.

The inequality of the radius vector would be somewhat different if the excentricity of the orbit in the second case were considerable, partly because the places of conjunction would not be at equal angular distances, partly because the disturbing forces would be different (as the distance between the satellites in conjunction would not always be the same), and partly because the effect of a given force is really different, according to the part of the orbit at which it acts. But where the excentricity is so small, as in the orbit of Jupiter's third satellite, or in those of the old planets, the alteration of the inequality of the radius vector produced by these differences is hardly sensible.

The reasoning of this note may be applied, with the proper alterations, to every case of perturbation, produced by a disturbing force which is nearly independent of the form of the orbit; and as this will apply successively to each of the causes producing disturbance, we shall at last arrive at the following general proposition: If several disturbing forces act on a planet or satellite, and if we estimate the inequality in the radius vector, which each of these would produce, supposing the orbit to have no excentricity independent of perturbation; then the inequality really produced, supposing the orbit to have an independent excentricity, will be nearly the same as the sum of all the inequalities so estimated.

It is to be remarked, that if an orbit have an independent excentricity, and if the orbit receive an alteration similar to an elliptic inequality (that is, if it be elongated on one side and flattened on the other), the orbit is still sensibly an ellipse, of which the original focus is still the focus. Thus, in the instance occupying the first part of this note, as the inequality impressed on the elliptic orbit in the second case is the same as the inequality in the first case, that is, is similar to an elliptic inequality, the orbit so altered will still be an ellipse, whose excentricity and line of apses are altered. We might, therefore, have obtained our results by at once investigating the alterations of the excentricity and line of apses produced by the disturbing forces; but the method adopted in the text is simpler.

We shall now proceed with the application of these conclusions to Jupiter's first three satellites.

(135.) The periodic time of Jupiter's first satellite is, 1 day, 18 hours, 27 minutes, and 34 seconds; that of the second satellite is, 3 days, 13 hours, 13 minutes, and 42 seconds; that of the third satellite is, 7 days, 3 hours, 42 minutes, and 32 seconds. The periodic time of the second satellite exceeds, by a small quantity, double that of the first, so that the preceding investigations apply to the motion of these two satellites. In fact, 275 revolutions of the first satellite are finished in almost exactly the same time as 137 revolutions of the second. If then, at a certain time, these two satellites start from conjunction, they will be in conjunction near the same place at every revolution of the second satellite, or at every second revolution of the first satellite: but the line of conjunction will regress slowly; and when the first satellite has finished 275 revolutions, or one revolution more than double the number made by the second satellite, they will again be in conjunction in the same place as before, the line of conjunction having regressed till it has again reached the same position; this takes place in 486½ days.

(136.) From the preceding investigation then it appears that, as these orbits have no excentricity independent of perturbation, they will be elliptic, and the line of apses of each orbit will regress so as to turn completely round in 486½ days; and that when in conjunction, the first satellite will always be in perijove, and the second satellite will always be in apojove.

(137.) But the periodic time of the third satellite is almost exactly double that of the second satellite, exceeding the double by a small quantity; and on this account the orbit of the second satellite will be distorted from the form which otherwise it would have had, by an inequality similar to that just investigated. In a word, the line of conjunction of the second and third satellites will slowly regress, and the orbit of the second satellite will always be compressed on the side next the points of conjunction, and elongated on the opposite side; and the orbit of the third satellite will always be elongated on the side next the points of conjunction, and compressed on the opposite side.

(138.) Now we come to the most extraordinary part of this theory. We have remarked that 275 revolutions of the first satellite are finished in almost exactly the same time as 137 revolutions of the second; but it will also be found that 137 revolutions of the second are finished in almost exactly the same time as 68 revolutions of the third: all these revolutions occupying 486½ days. Because 275 exceeds the double of 137 by 1, we have inferred that the line of conjunctions of the first and second satellites regresses completely round in 275 revolutions of the first satellite, or in 486½ days. In like manner, because 137 exceeds the double of 68 by 1, we infer that the line of conjunctions of the second and third satellites regresses completely round in 137 revolutions of the second satellite, or in 486½ days. Hence we have this remarkable fact: *the regression of the line of conjunction of the second and third satellites is exactly as rapid as the regression of the line of conjunction of the first and second satellites.* So accurate is this law, that in the thousands of revolutions of the satellites, which have taken place since they were discovered, not the smallest deviation from it (except what depends upon the elliptic form of the orbit of the third satellite) has ever been discovered.

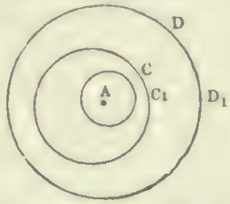
(139.) Singular as this may appear, the following law is not less so. *The line of conjunction of the second and third satellites always coincides with the line of conjunction of the first and second satellites produced backwards, the conjunctions of the second and third satellites always taking place on the side opposite to that on which the conjunctions of the first and second take place.* This defines the relative position of the lines of conjunction, which (by the law of last article) is invariable. Like that law it has been found, as far as observation goes, to be accurately true in every revolution since the satellites were discovered.

(140.) The most striking effect of these laws in the perturbations of the satellites is found in the motions of the second satellite. In consequence of the disturbing force of the first satellite, the orbit of the second satellite will be elongated towards the points of conjunction of the first and second (130), and consequently compressed on the opposite side. In consequence of the disturbing force of the third satellite, the orbit of the second satellite will be compressed on the side next the points of conjunction of the second and third (128). And because the points of conjunction of the second and third are always opposite to the points of conjunction of the first and second, the place of compression from one cause will always coincide with the place of compression from the other cause; and therefore the orbit of the second satellite will be very much compressed on that side, and consequently very much elongated on the other side. The excentricity of the orbit, depending thus entirely on perturbation, exceeds considerably the excentricity of the orbit of Venus. The inequalities in the motions of the satellites, produced by these excentricities, were first discovered (from observation) by Bradley about A.D. 1740, and first explained from theory by Lagrange, in 1766.

(141.) The singularity of these laws, and the accuracy with which they are followed, lead us to suppose that they do not depend entirely on chance. It seems natural to inquire, whether some reason may not be found in the mutual disturbance of the satellites, for the preservation of such simple relations. Now we are able to show that, supposing the satellites put in motion at any one time, nearly in conformity with these laws, their mutual attraction would always tend to make their motions follow these laws exactly. We shall show this by supposing a small departure from the law, and investigating the nature of the forces which will follow as a consequence of that departure.

(142.) Suppose, for instance, that the third satellite lags behind the place defined by this law; that is, suppose that when the second satellite is at the most compressed part of its ellipse, (as produced by the action of the first satellite,) the third satellite is behind that place. The conjunction then of the second and third satellites will happen before reaching the line of apses of the orbit of the second, as produced by the action of the first. Now in the following estimation of the forces which act on the third satellite, and of their variation depending on the variation of the positions of the lines of conjunction, there is no need to consider the influence which the ellipticity of the orbit of the second as produced by the third, or that of the third as produced by the second, exerts upon the third satellite; because the flattening arising from the action of the third, and the elongation arising from the action of the second, will always be turned towards the place of conjunction of the second and third, and the modification of the action produced by this flattening and elongation will always be the same, whether the lines of conjunction coincide or not. In *fig.* 37, let C be the perijove of the orbit of the second satellite, (as produced by the action of the 1st satellite alone,) D the point of the orbit of the third, which is in the line A C produced. If the third satellite is at D when the second is at C, the force produced by the second perpendicular to the radius vector, retards the third before it reaches D, and accelerates it after it has passed D, by equal quantities. But if, as in the supposition which we have made, the conjunction takes place in the line $A\ C_1\ D_1$, the retardation of the third satellite before conjunction is produced by the attraction of the second satellite before it arrives at perijove, when it is near to the orbit of the third satellite, (and therefore acts powerfully,) and moves slowly, (and therefore acts for a long time); while the acceleration after conjunction is produced by the second satellite near its perijove, when it is far from the orbit of the third satellite, (and therefore acts weakly,) and moves rapidly (and therefore acts for a short time). The retardation therefore exceeds the acceleration; and the consequence is, by (48), that the periodic time of the third satellite is shortened, and therefore its angular motion is quickened; and therefore, at the next conjunction, it will have gone further forward before the second satellite can come up with it, or the line of conjunction will be nearer to the place of perijove of the second satellite, depending on the action of the first. In the same manner, if we supposed the third satellite moving rather quicker than it ought in conformity with the law, the tendency of the forces would be to accelerate it, to make its periodic time longer, and thus to make its angular motion slower. By the same kind of reasoning it will be seen that there are forces acting on the first satellite, produced by the elliptic inequality which the third impresses on the orbit of the second, tending to accelerate the angular motion of the first satellite in the first case, and to retard it in the second. The same reasoning will also show that both the first and third satellites exert forces on the second, tending to retard its angular motion in the first case, and to accelerate it in the second. All these actions tend to preserve the law: in the first case by making the line of conjunctions of the first and second satellite regress, and that of the second and third progress, till they coincide; and in the second case, by altering them in the opposite way, till they coincide.

Fig. 37.



(143.) Perhaps there is no theoretical permanence of elements on which we can depend with so great certainty, as on the continuance of this law. The greatest and most irregular perturbations of Jupiter or of his satellites, provided they come on gradually, will not alter the relation between their motions; the effect of a resisting medium will not alter it; though each of these causes would alter the motions of all the satellites; and though similar causes would wholly destroy the conclusions which mathematicians have drawn as to the stability of the solar system, with regard to the elements of the planetary orbits. The physical explanation of this law was first given by Laplace, in A.D. 1784.

(144.) We have terminated now the most remarkable part of the theory of these satellites. There are however some other points which are worth attending to, partly for their own sake, and partly as an introduction to the theory of the planets.

(145.) The orbit of the third satellite, as we have mentioned, has a small excentricity independent of perturbation. Consequently, when the conjunction with the second takes place near the independent perijove of the third, the effect of the disturbance on the second is rather greater than at any other time; and this produces an irregularity in the excentricity of the second, and in the motion of its apses, depending on the distance of the line of conjunction from the independent perijove of the third. The departure from uniformity in the angular motion of the third also produces a departure from uniformity in the regression of the line of conjunction, and this contributes to the same irregularity.

(146.) The disturbing force in the direction of the radius vector, produced by an inner satellite, is sometimes directed to the central body and sometimes from it; but on the whole the former exceeds the latter (80). Now the principal part of the effect really takes place when the satellites are near conjunction; consequently, when the line of conjunction passes near the independent perijove of the third satellite, the force by which the third satellite is urged to the planet is greater than at any other time; and as the line of conjunction revolves, the force alternately increases and diminishes. This produces an irregularity in the major axis, and consequently in the motion of the third satellite (47), depending on the distance of the line of conjunction from the perijove of the third.

(147.) The disturbing force in the direction of the radius vector produced by an outer satellite is sometimes directed to the central body and sometimes from it; but on the whole the latter exceeds the former (80). For the reasons therefore, in the last article, there is in the motion of the second satellite an irregularity depending on the distance of the line of conjunction from the independent perijove of the third, but opposite in its nature to that of the third satellite.

(148.) Each of these irregularities in the motion of one of these satellites produces an irregularity in the motion of the others; and thus the whole theory becomes very complicated when we attempt to take the minute irregularities into account.

(149.) The motion of the fourth satellite is not related to the others in the same way in which they are related among themselves. Its periodic time is to the periodic time of the third nearly in the proportion of 7 : 3. Some of the irregularities then which it experiences and which it occasions are nearly similar to those in the motions of the planets. These however are small: the most important are those depending on the changes in the elements which require many revolutions of the satellites to go through all their various states, but which nevertheless have been observed since the satellites were discovered. We shall proceed with these.

(150.) First, let us suppose that the third satellite has no excentricity independent of perturbation, and that the fourth satellite has a sensible excentricity, its line of apses progressing very slowly, in consequence principally of the shape of Jupiter (so slowly as not to have gone completely round in eleven thousand revolutions of the satellite). When each of the satellites has revolved a few hundred times round Jupiter, their conjunctions will have taken place almost indifferently in every part of their orbits. If the orbit of the fourth as well as that of the third had no independent ellipticity, there would be no remarkable change of shape produced by perturbation, as the action of one satellite upon the other would be the same when in conjunction in all the different parts of the orbit. But the orbit of the fourth being excentric, the action of each satellite on the other is greatest when the conjunction happens near the perijove of the fourth satellite. We may consider then that the preponderating force takes place at this part of the orbits; and we have to inquire what form the orbit of the third satellite must have, to preserve the same excentricity at every revolution. It must be remembered here that the effect of Jupiter's shape is to cause a more rapid progress of the line of apses of the third satellite, if its orbit be excentric, than of the line of apses of the fourth.

(151.) Considering then that the preponderating force on the third satellite in the direction of the radius vector is directed from the central body towards the perijove of the fourth, and that the preponderating force perpendicular to the radius vector accelerates it as it approaches that part, and retards it afterwards, it is plain from (51), (65), and (66), that if the perijove of the third satellite were in that position, the forces would cause the line of apses to regress; and this regression, if the excentricity of the third be small, may be considerable (though the preponderance of force which causes it is extremely small), and may overcome so much of the progression caused by Jupiter's shape, as to make the real motion of the line of apses as nearly equal as we please to the motion of the line of apses of the fourth. But the motion of the line of apses of the fourth will itself be affected (though very little) by the greater action of the third satellite on it at the same place; and the part in the radius vector being directed at its perijove to the central body, and the part perpendicular to the radius vector retarding it before it reaches the perijove, and accelerating it afterwards, will cause a small increase of progression of its apse. The state of things will be permanent, so far as depends on these forces, when the increased progression of the apse of the fourth satellite is equal to the diminished progression of the apse of the third; and thus the progression of the apse of the fourth will be somewhat increased, and the third satellite's orbit will have a compression corresponding in direction to the perijove of the fourth, and an elongation in the same direction as the apojove of the fourth. This would be the case if the third satellite had no excentricity independent of perturbation; but we may, as in other cases, consider that the same kind of distortion will be produced in the orbit if it has an independent excentricity.

(152.) Now let us suppose the fourth satellite to have no excentricity independent of perturbation, and the third satellite to have an independent excentricity. The greatest action will now be at the apojove of the third satellite, and this will (though in a small degree) cause the line of apses of the third satellite to progress; that is, it will increase the rapidity of progression which Jupiter's shape gives it. If now we wish to discover the form of orbit of the fourth satellite which will at every revolution preserve the same excentricity, and have its line of apses always corresponding with that of the third satellite, and therefore progressing more rapidly than the shape of Jupiter alone would make it progress, we must evidently suppose the perijove of the fourth satellite turned towards the apojove of the third, and, by supposing the excentricity small enough, the progression may be made as rapid as we please. Thus the effect of excentricity in the orbit of the third satellite is, that its line of apses is made to progress rather more rapidly, and that the orbit of the fourth satellite is compressed on the side next the apojove of the third satellite, and elongated on the opposite side. We have supposed for this investigation that the fourth satellite had no excentricity independent of perturbation, but the conclusion as to the distortion of the orbit may be applied if we suppose it to have independent excentricity.

(153.) In fact, the orbits of both the third and fourth satellites have independent excentricities, and both our conclusions apply to them. The fourth satellite, besides its independent excentricity, has an excentricity impressed upon it, opposite in kind to that of the third; and the third satellite, besides its independent excentricity, has an excentricity impressed upon it of the same kind as that of the fourth. In the same manner, the orbits of the first and second satellites have small excentricities impressed on them, similar in their kind to those of the third and fourth.

(154.) It will readily be conceived that the excentricities of the orbit of the third satellite will affect the great inequality (137) which it produces in the motion of the second; and on the contrary, that the inequality in the motion of the third produced by the attraction of the second, will influence the effect of the third on the fourth. We shall not however notice these further than to state that their effects are small.

(155.) We have now gone over the principal inequalities of the motions of Jupiter's satellites. They are so much connected, and (as we may say) so completely entangled, that though they may be explained in the way in which we have considered them, it would hardly be possible to calculate them in that way. A mathematical process of the most abstruse kind, which will at the same time embrace the motions of all, is alone competent to this object. We shall however have attained our end if we have given the reader a general idea of the explanation of disturbances in the most curious and complicated system that has ever been reduced to calculation.

SECTION VII.—*Theory of Planets.*

(156.) The theory of the planets may be considered as holding a middle place between that of our moon and that of Jupiter's satellites. In our moon, the principal inequalities are those that exhibit themselves in nearly the same order at every revolution, or, at longest, in the earth's revolution round the sun, depending entirely upon the relative position of the moon, the sun, and the lines of apses. In Jupiter's satellites, some of the principal inequalities (as those of the third and fourth satellites) do not depend at all upon the relative position of the bodies, but depend on the position of the lines of apses, whose revolutions, though slow, may yet be completely observed. But in the planets the terms analogous to those which we have mentioned in the moon's motions are small; the changes of elements are so slow, that though they may be in some degree observed, many thousands of years would be necessary to observe them completely. The most remarkable irregularities are those produced by changes in the elements occupying several revolutions of the planets, and more nearly analogous to the mutual perturbations of the three first satellites of Jupiter than to any other that we have seen; differing from them however in this respect, that for most of them independent excentricities are quite essential.

(157.) There are, however, some terms very nearly similar to those mentioned in the theory of the moon. Suppose, for instance, we consider the perturbations of Mercury by Jupiter (whose distance from the sun is more than thirteen times as great). This case is almost exactly analogous to the case of the moon disturbed by the sun. And in consequence, Mercury's orbit is flattened a little on the sides nearest to and farthest from Jupiter; but this effect is much disguised by the effect of forces analogous to those mentioned in (94), which here preponderates greatly: his line of apses progresses a little at every revolution, when Jupiter is nearly in that line, and regresses a little when Jupiter is in the line perpendicular to it: his orbit is a little more excentric in the former case, and a little less so in the latter; and his orbit is a little larger when Jupiter is at perihelion than when at aphelion. The same thing applies very nearly to the disturbances of Venus, the Earth, and Mars, produced by Jupiter.

(158.) The instance taken above is almost an extreme one. When we consider the perturbations of two planets which are nearer to each other, we are obliged to alter our conclusions considerably. The disturbing force becomes so much greater where the planets are near conjunction than at any other part, that the orbit is much more changed there than at any other part. However, the reasoning upon which, in (91), we determined the form of the moon's orbit, laying aside the consideration of independent excentricity, will, to a certain extent, apply here. The orbit in several cases will be flattened on the side where conjunction takes place, and on the opposite side, but generally most so on the latter; and will be made protuberant at the parts where the disturbing force tends wholly to increase the gravitation towards the sun. The same general reasoning will, in many cases, help us to find the form of the orbit which is influenced by the attraction of an interior planet.

(159.) A consideration, however, of particular cases will show how cautious we must be in applying this conclusion. Suppose, for instance, we consider the reciprocal perturbations of the Earth and Mars. The periodic time of Mars is nearly double that of the Earth. Here, then, we fall upon an inequality of the same kind as that discussed in (122), &c., for the satellites of Jupiter. And though the periodic time of Mars is not *very* nearly double that of the Earth, so that the distortions produced in the orbits of the Earth and Mars are not very striking; still they are the greatest (of those depending only on the position of the planets) which these two bodies produce in each other's motions. Here, then, the disturbance, which on a hasty view we might suppose analogous to the *variation* of the Moon, becomes, from the small disproportion of distances, and the near commensurability of the periodic times, much more nearly similar to the slow variation of the elements of orbits.

(160.) It seems quite hopeless to attempt to give a notion of the calculations by which, in all the different cases, the disturbances independent of the excentricities can be computed. It is sufficient to state, that the same methods apply to all, and that they are much more simple than those relating to other points, of which an idea may be given by general explanation.

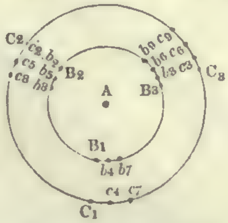
(161.) Let us now consider the inequalities of motion which depend on the excentricities and inclinations of the planets' orbits. The idea that will probably first occur to the reader is this. "If the disturbances of the planets, supposing their orbits to have no independent excentricities, amount only to a few seconds, how is it likely that the small alterations of place, which are produced by the trifling excentricities and inclinations of their orbits, will so far alter their forces upon each other as to produce any sensible difference in the magnitude of irregularities which are already insignificant?" In answer to this we must say, "It is true that these forces, or alterations of forces, are exceedingly small, and those parts of them which act in the same direction for a short time only (as for a fraction of the periodic time of a planet) do not produce any sensible effect. But we can find some parts of them which act in the same manner during many revolutions; and this in many cases where no disturbance can be found, independent of the excentricities, similar to those discussed in (122), &c.; the effects of these may grow up in time to be sensible; and those in particular which alter the mean distance and the periodic time may produce in time an effect on the longitude of the planet (49), very much more conspicuous than that in the alteration of the orbit's dimensions."

(162.) In this consideration is contained the whole general theory of those inequalities known by the name of *inequalities of long period.* They are the only ones depending on the excentricities (besides those similar to the moon's evection) which ever become important.

(163.) To enter more minutely into the explanation, let us take the instance of the long inequality of Jupiter and Saturn: the most remarkable for its magnitude, and for the length of time in which the forces act in the same manner, as well as for the difficulty which it had given to astronomers before it was explained by theory, that has been noticed since the first explanation of the Moon's irregularities.

(164.) The periodic times of Jupiter and Saturn are very nearly in the proportion of 2 to 5 (the periodic times being 4332 days, 17 hours, and 10,759 days, 5 hours), or the number of degrees of longitude that they will describe in the same time, omitting all notice of their excentricities, will be in the proportion of 5 to 2 nearly. Suppose, now, that they were exactly in the proportion of 2 to 5; and suppose that Jupiter and Saturn started from conjunction; when Saturn has described 240 degrees, Jupiter will have described 600 degrees (as these numbers are in the proportion of 2 to 5); but as 360 degrees are the circumference, Jupiter will have gone once round, and will besides have described 240 degrees. It will, therefore, again be in conjunction with Saturn. When Saturn has again described 240 degrees, that is, when Saturn has described in all 480 degrees, or has gone once round and has described 120 degrees more, Jupiter will have described 1200 degrees, or will have gone three times round and described 120 degrees more, and, therefore, will again be in conjunction with Saturn. When Saturn has again described 240 degrees, that is, when it has gone exactly twice round, Jupiter will have gone exactly five times round, and they will again be in conjunction. So that, if the periodic times were exactly in the proportion of 2 to 5, there would be a continual succession of conjunctions at the points whose longitudes exceeded the longitude of the first place of conjunction by 240°, 120°, 0°, 240°, 120°, 0°, &c. Thus, in *fig.* 38, if B_1 is the place of Jupiter at first, and C_1 that of Saturn, Jupiter will have gone quite round, and also as far in the next revolution as B_2, while Saturn has described part of a revolution only to C_2: then Jupiter will again have gone quite round, and also as far in the next revolution as B_3, while Saturn has described part of a revolution to C_3: then Jupiter will have performed a whole revolution, and part of another to B_1, while Saturn has performed part of a revolution to C_1: and then the same order of conjunctions will go on again. If, then, the periodic times were exactly in the proportion of 2 to 5, the conjunctions would continually take place in the same three points of the orbits. This conclusion will not be altered by supposing the orbits excentric: for though the places of conjunction may then be somewhat altered, the conjunctions, after the third (when Saturn has gone round exactly twice, and Jupiter exactly five times), will go on in the same order, and happen at the same places as before.

Fig. 38.



(165.) But the periodic times are not exactly in the proportion of 2 to 5, but much more nearly in the proportion of 29 : 72. This alters the distance of the places of conjunction. We must now suppose Saturn to move through 242°·79, and Jupiter (by the proportion just mentioned) will then have moved through 602°·79, or through a whole circumference and 242°·79, and they will be in conjunction again. The next conjunction will take place when Saturn has moved through double this angle, or 485°·58, or when Saturn has performed a whole revolution, and 125°·58 of the next revolution: and the following conjunction will take place when Saturn has moved through 728°·37, or when Saturn has gone twice round, and has described 8°·37 more. Now, then, the same order of conjunctions will not go on again at the same places as before, but the next three after this will be shifted 8°·37 before the former places, the three following the last-mentioned three will be again shifted 8°·37, and so on. The places of successive conjunction, in *fig.* 38, will be at B_1 C_1, b_2 c_2, b_3 c_3, b_4 c_4, b_5 c_5, b_6 c_6, &c. The shifting of the places of conjunction will take place in nearly the same manner, whether the orbits are excentric or not.

(166.) From this the following points are evident:—

First. In consequence of the periodic times being nearly in the proportion of 2 to 5, many successive conjunctions happen near to three equidistant points on the orbits.

Secondly. In consequence of the proportion being not exactly that of 2 : 5, but one of rather less inequality, the points of conjunction shift forward, so that each successive set of conjunctions is at points of the orbits more advanced, by 8°·37, than the preceding one.

(167.) Let us now inquire how long it will be before the conjunctions happen at the same parts of the orbits as at first.

This will be when the series of points b_4, b_7, b_{10}, &c., extends to B_2. For then the series b_5, b_8, b_{11}, &c., will extend to B_1, and the series b_3, b_6, b_9, &c., will extend to B_2. The time necessary for this will be gathered from the consideration, that in three conjunctions the points are shifted 8°·37: and that the points must shift 120° from B_1, before they reach B_2: and that we may, therefore, use the proportion, As 8°·37 is to 3, so is 120° to 43 nearly, the number of conjunctions that must have passed before the points of conjunction are again the same. And as Saturn advances 242°·79 between any conjunction and the next, he will, at the forty-third conjunction from the first, have described 10440°, or 29 circumferences; and Jupiter, therefore (by the proportion of their periodic times), will have described 72 circumferences. The time, then, in which the conjunctions return to the same points is twenty-nine times Saturn's periodic time, or seventy-two times Jupiter's periodic time, or about 855 years.*

(168.) Now let us examine into the effects of this slow motion of the points of conjunction upon the forces which one body exerts to disturb the other.

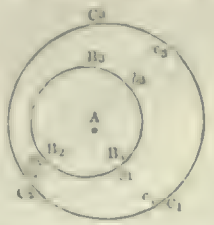
(169.) If the orbits had no independent excentricity, it would affect them no further than by the periodical distortion which would take place at every conjunction. There would be nothing in one set of conjunctions, more than in another, which could affect the dimensions of the orbits.

(170.) But if the orbits are not circular, this is no longer true. It is not the same thing whether the conjunctions take place at B_1 C_1, B_2 C_2, and B_3 C_3, *fig.* 39, or at b_1 c_1, b_2 c_2, and b_3 c_3. The distances of the planets are not the same, and consequently the forces which they exert on each other are not the same; also their velocities are different in different parts of their orbits, or at different points of conjunction, and therefore the times during which they can act on each other are not the same. It is true that, in the figure, the distance at $b_2 c_2$ is less than at $B_2 C_2$, while that at $b_3 c_3$ is greater than at $B_3 C_3$; and thus there is a partial compensation in the changes of the effects produced in different points of the orbit. But it can be discovered only by very complete calculations, whether the compensation is perfect or not. The calculations necessary for this purpose are probably the most complicated that physical science has ever given occasion for; and the reader must not here expect the smallest account of them. This only can be stated as a result, that in no instance in the planetary system is the compensation perfect, and that the chances for its being perfect in any case are infinitely small.

---

* These numbers are not quite exact: the proportion of 29 : 72 not being quite accurate.

Fig. 39.



(171.) We have here considered the varying influence of one body on the other at conjunction, as depending entirely on the excentricities of the two orbits. But there is another circumstance which may also cause the influence to vary. The orbits may be inclined, and this will affect both the distance of the bodies and the direction in which they attract each other.

(172.) In the case, then, of Jupiter and Saturn, we have the two planets acting on each other with forces which are nearly the same at every third conjunction, but are not exactly the same, and whose variations occupy a period of 850 years. Of these forces, parts are in the direction of the radius vector, and these tend directly to affect the major axes of the orbits described: other parts are perpendicular to the radius vector, sometimes accelerating and sometimes retarding; and these tend (though in opposite ways) to affect the major axes of the orbits. There are, therefore, forces tending to alter the major axes of the orbits, which go through all their changes only in 850 years. During half of this time they tend to make the major axis of Jupiter's orbit less, and that of Saturn's orbit greater; and during the other half they tend to make the major axis of Jupiter's orbit greater, and that of Saturn's orbit less. This coincidence, in time, of the increase of one major axis with the decrease of the other, is the result of investigations that we cannot explain here.

(173.) After the partial compensation that we have mentioned, it will readily be understood that the varying force which produces these effects is small: so small, indeed, is it, that after acting more than 400 years, it has increased (or diminished) the major axis of Saturn's orbit only by $\frac{1}{1350}$th part, and diminished (or increased) that of Jupiter's orbit only by [illegible]th part. These alterations would hardly be discoverable with our best instruments. But during 400 years the major axis of each orbit differs from the major axis during the next 400 years by a part of these quantities. The planet's rate of annual angular motion is, for 400 years, constantly less than its average rate; and for the next 400 years it is constantly greater than its average rate; and in this length of time the inequality in longitude may (49) grow up into a most formidable quantity. In fact, the inequality thus produced in Saturn's longitude amounts to about 48′, by which its true place is sometimes before and sometimes behind its mean place: that in Jupiter's longitude amounts to about 21′. (The greatest inequality of any other planet does not exceed 3′, and the greatest of the planets inferior to Jupiter does not exceed 25″.) The theoretical explanation of these inequalities was first given by Laplace in 1785.

(174.) The magnitude of these inequalities in the motions of Jupiter and Saturn, as we have seen, depends principally on the length of time during which the forces act in the same manner; first, because in this long time they can produce a sensible alteration in the major axis and annual angular motion; secondly, because the two planets move for so long a time with this altered angular motion. But it must also be borne in mind that these two planets are by far the largest in the system; the mass of Jupiter being 300 times that of the earth, and the mass of Saturn being 100 times that of the earth (the next of the planets in the order of magnitude, except Uranus).

(175.) The same general reasoning, by which we have shown that there is a periodical inequality of the major axis of either of these orbits, will also show that there is a periodical inequality in the excentricity and in the place of the perihelion. It will also appear, in the same way, that these effects are the remainder, after partial compensation of effects in different parts of the orbit. Thus if one conjunction happen when Jupiter is going towards aphelion, the effect of Saturn's disturbing force is to pull Jupiter from the sun; and, therefore, by (59), to increase the excentricity of Jupiter's orbit. But it is then perfectly certain that either the next conjunction, or the next but one, or perhaps both these, will happen at a part where Jupiter is going towards perihelion; and then, by (59), the excentricity of Jupiter's orbit is diminished. Similar reasoning applies to the excentricity of Saturn's orbit. It becomes, then, a matter of calculation, whether the compensation is perfect or not. Now it appears, upon investigation, that the compensation is not perfect, but that, while the points of conjunction shift through 120°, the effect of the uncompensated part is, for half the time, to increase the excentricity, and for half the time to diminish it. It appears, also, that there is no necessary connection between the time at which the excentricity is greatest or least, and that when the major axis is greatest or least; so that we cannot assert that when the major axis is greatest the excentricity is greatest, or the contrary, or that the excentricity of one is greatest when that of the other is greatest: all that we can assert is, that the excentricity of each orbit occupies the same time in going through its changes from greatest to least, as the major axis occupies in going through its change from greatest to least. The effect on the planet's distance from the sun, produced by the change of excentricity, is much more considerable than that from the change in the major axis; being for Jupiter $\frac{1}{1130}$ of his whole distance, and for Saturn $\frac{1}{377}$ of his whole distance.

(176.) Similar remarks apply, in every respect, to the motion of the perihelion of each orbit. Each is made to progress during 425 years and to regress during 425 years; but there is no necessary relation between the time when one has progressed furthest and the time when the other has progressed furthest. There is, however, a necessary relation between the change of excentricity and the motion of the perihelion of each orbit: the excentricity of either orbit has its mean value when the perihelion of that orbit has progressed furthest or regressed furthest; and when the excentricity is either greatest or least, the perihelion is at its mean place.

(177.) We have taken the long inequality of Jupiter and Saturn as the most imposing by its magnitude, and the most celebrated for its history (as, before it was explained theoretically, astronomers were completely bewildered by the strange irregularity in the motion of these planets). But there are several others which, in theory, are as curious. Eight times the periodic time of the earth is very nearly equal to thirteen times the periodic time of Venus; and this produces, in the motions of the earth and Venus, a small inequality, which goes through all its changes in 239 years. Four times the periodic time of Mercury is nearly equal to the periodic time of the earth, and this produces an inequality whose period is nearly 7 years. The periodic time of Mars is nearly double of the earth's, and this produces a considerable inequality, depending on the excentricities, &c., besides that mentioned in (159), which was independent of the excentricities. Twice the periodic time of Venus is nearly equal to five times that of Mercury; three times the periodic time of Venus is nearly equal to that of Mars; three times the periodic time of Saturn does not much differ from that of Uranus. Each of these approximations to equality gives rise to an equation of sensible magnitude, and of long period, in the motion of both planets.

(178.) But it will easily be seen that the defect of compensation, on which the effects depend, is much greater in some cases than in others. The conjunctions of the earth and Mars take place at only one point, and the points near it, for several revolutions; those of Venus and Mars take place only at two opposite points and their neighbourhood (as each successive conjunction takes place when Mars has described half a revolution, and Venus 1½ revolution); those of Jupiter and Saturn, as we have seen, at three points; those of Venus and the earth at five points. It is evident that, in the first of these, the whole effect of the change of one point of conjunction has its influence in altering the orbit's dimensions; that in the second there is only the difference between two effects; that in the third there is the mixture of three, which tend to balance; that in the next there is the mixture of five in the same way. The smaller, then, is this number of points, the more favourable are the circumstances (supposing the same length of period for the inequality) for producing a large inequality. This number of points is always the same as the difference between the two least numbers, expressing nearly the proportion of the periodic times. Thus we may expect to find a large inequality when the periodic times of two planets are very nearly in the same proportion as two numbers, whose difference is small.

(179.) We shall now proceed to mention the *secular* variations of the elements of the orbits of planets. By this term is meant those variations which do not depend upon the positions of the planets in their orbits, or the places of conjunction, but merely upon their relative distances and excentricities, and the positions of their lines of apses. They are, therefore, the variations which depend upon the mean or average action of one planet upon another in the long run: all the sensible departures from the secular variation, produced by the irregularity of the action of one planet upon another, being supposed to be contained in the inequalities already discussed.

(180.) First, then, with regard to the mean distance of a planet. If we consider an exterior planet disturbing an interior one (as Saturn disturbing Jupiter), the disturbing force in the direction of the radius vector, by (77), &c., tends sometimes to draw it from the sun, sometimes to draw it towards the sun; but the former is the greater, and we may therefore consider the force as, upon the whole, diminishing the sun's attraction. This, by (46), alters the relation between the periodic time and the mean distance, so that the mean distance is less than it would have been with the same periodic time, had there been no disturbance. If we consider an interior planet disturbing an exterior one (as Jupiter disturbing Saturn), the disturbing force tending to draw it to the sun is greatest; and here the mean distance is greater than it would have been with the same periodic time, had there been no disturbance. But so long as these general effects in the force directed to the sun continue unaltered, the mean distances will not alter (46), &c. Now, upon taking a very long period (as several thousand years), it is easy to see that, if we divide that period into two or three parts, the two planets have in each of those two parts been in conjunction indifferently in all parts of their orbits; that they have had every possible relative position in every part; and that (if we make the periods long enough) the force which one planet has sustained in any one point will be accurately the mean of all which it would sustain, if we estimated all those that it could suffer from supposing the other planet to go with its usual motion through the whole of its orbit. As this mean will be the same for each of the periods, there will, in the long run, be no alteration of the force in the direction of the radius vector, and we may assert at once that the mean distance cannot be altered by it.

(181.) But with regard to the disturbing force acting perpendicularly to the radius vector, the circumstances are different. The mere existence of such a force, without variation, causes an alteration in the mean distance (48); and it is necessary to show that the nature and variations of the force are such that, in the long run, the velocity of the disturbed planet is not affected by it. For this purpose, instead of considering merely the disturbing force perpendicular to the radius vector, we will consider separately the whole force which the disturbing planet exerts on the sun, and the whole force which it exerts on the disturbed planet. Now, the force which it exerts on the sun tends to pull the sun sometimes in one direction and sometimes in another, but on the whole produces no permanent displacement: this force, then, may at once be neglected. The force which one planet has exerted on the other has acted when, for any arbitrary position of the disturbing planet, the disturbed planet has been at every point of its orbit. Since the whole acceleration produced in a long time is the sum of all the accelerations diminished by the sum of all the retardations, we may divide them into groups as we please, and sum each group. Let us, then, group together all the accelerations and retardations produced in one position of the disturbing planet. The disturbed planet having been in every small part of its orbit, during a time proportional to the time which it would occupy in passing through that small part in any one revolution, the various accelerations and retardations will bear the same proportion as if the disturbed planet had made one complete revolution, and the disturbing planet had been fixed. Now, it is a well-known theorem of mechanics, that when a body moves through any curve, acted on by the attractions of any fixed bodies, its velocity, when it reaches the point from which it started, is precisely the same as when it started: the accelerations and retardations having exactly balanced. Consequently, in the case before us, if the disturbing planet had been fixed, and the disturbed planet had made one complete revolution, the latter would, on the whole, have been neither accelerated nor retarded; and, therefore, in the long run, all the accelerations and retardations of the disturbed planet, produced in any arbitrary position of the disturbing planet, will exactly balance. The same may be shown for every position of the disturbing planet; and thus, on the whole, there is no alteration of velocity. Since, then, in the long run, the planet's velocity is not altered, and since (180) the force directed to the sun is not altered, the planet's mean distance will not be altered. This reasoning does not prevent the increase or diminution of the velocity at particular parts of the orbit, and therefore the excentricity and the line of apses may vary; but it shows that, if there is an increase at one part, there is a diminution that balances it at another; and at the point where the orbit at the beginning of a long time and the orbit at the end of that time intersect (which will be at mean distance nearly) the velocity will not be altered.

Our demonstration supposes that the portions of the curves described in different revolutions, for the same position of the disturbing planet, are parts of one orbit, and therefore does not take account of the alteration in the magnitude of the disturbing force produced by the alteration of place which that force has previously caused. This has been taken into account, to a certain degree, by several mathematicians; and it appears, as far as they have gone, that this produces no alteration in the conclusion.

(182.) Secondly, as to the place of perihelion, or the position of the line of apses. The motion of this will depend essentially on the excentricity of the orbit of the disturbing planet. Suppose, for instance, that the orbit of Venus was elliptical and the earth's orbit circular; as the distance of these planets in conjunction is little more than one-fourth of the earth's distance from the sun, the ellipticity of the orbit of Venus would bring that planet at aphelion so much nearer to the earth's orbit, that by far the greatest effect would take place when in conjunction there; and this, by (54), would make Venus' line of apses progress. But if the earth's orbit were more elliptic than that of Venus, and if the earth's perihelion were on the same side of the sun as the perihelion of Venus, it might happen that the principal action would take place at perihelion, and then, by (51), the line of apses would regress. These effects would continue to go on, while the relative position of the lines of apses, and the proportion of the excentricities, remained nearly the same. As, in the long run, conjunctions would happen everywhere, the preponderating effect would be similar to the greatest effect; and thus the secular motion of the line of apses will be constant (till the positions of the lines of apses, &c., shall have changed considerably); its magnitude and direction will depend on the excentricities of both orbits; but if the disturbed planet is the interior, and if the orbit of the other be not excentric, the line of apses will progress. The same is true if the disturbed planet is exterior (the greatest action being then at the perihelion, if the interior orbit have no excentricity, and being directed to the sun).

(183.) Thirdly, as to the excentricity. If the orbit of the disturbing planet were circular, the effect on the excentricity produced by conjunction at the place where the orbits are nearest, would be of one kind before conjunction, and of the opposite kind after conjunction, from the disturbing force in the radius vector; and thus the excentricity would not be altered. The same would happen if both orbits were excentric, provided their lines of apses coincided. Thus it appears that there is no variation of excentricity, except the orbit of the disturbing planet is excentric, and its line of apses do not coincide with that of the disturbed planet. When these conditions hold (as they do in every planetary orbit), a general idea of the effect may be obtained by finding where the orbits approach nearest; then, if we consider the disturbance of the interior planet, since the force draws it from the sun, the excentricity will be increased if it is moving from perihelion, or diminished if it is moving towards perihelion. For the exterior planet, as the force draws it towards the sun, the conclusion will be of the opposite kind. These effects are constant, till the excentricities and the positions of the lines of apses have changed sensibly. The place where the force at conjunction produces the greatest effect on the excentricity may not be strictly the place where the orbits are nearest, but probably will not be far removed from that place.

At the place where the orbits approach nearest, both planets in general are moving from perihelion, or both towards perihelion, so that when one excentricity is increased, the other is diminished.

(184.) For the general stability of the planetary system, the positions of the lines of apses are not important, but the permanency of the major axes and the excentricities are of the greatest importance. The conclusion which we have mentioned as to the absence of secular variation of the major axis, from the action of one planet, applies also to the disturbances produced by any number of planets, and thus we can assert that the major axes of the orbits of the planets are not subject to any secular variation. The excentricities are subject to secular variation, but even this corrects itself in a very long time: when the investigation is fully pursued, it is found that each of the excentricities is expressed by a number of periodic terms, the period of each being many thousands of years. Thus the major axis of the earth's orbit, notwithstanding its small and frequent variations, has not sensibly altered in many thousands of years, and will not sensibly alter; the excentricity, besides suffering many small variations, has steadily diminished for many thousands of years, and will diminish for thousands of years longer, after which it will again increase.

(185.) A remarkable relation exists between the variation of the excentricities (of which that mentioned in (183) is a simple instance), the result of which, as to the state of the excentricities at any time, is given thus: The sum of the products of the square of each excentricity by the mass of the planet, and by the square root of the major axis, is always the same.

Section VIII.—*Perturbation of Inclination and Place of Node.*

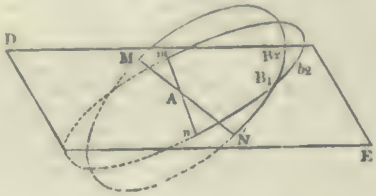
(186.) We have hitherto proceeded as if the sun, the moon, and all the planets, revolved in the same plane—as if, for instance, the sun were fixed in the centre of a table, and all the planets, with their satellites, revolved on the surface of the table. But this supposition is not true. If we suppose the earth to revolve on the surface of the table, the moon will, in half her revolution (we mean while she describes 180°, not necessarily in half her periodic time), rise above the table, and in the other half she will go below it, crossing the surface at two points which, as seen from the earth, are exactly opposite. Venus will, in half her revolution, rise above the table, and in half will sink below it, crossing the table at two points which, as seen from the sun, are exactly opposite; each of the other planets and satellites in like manner crosses the plane at points which, as seen from the central body, are exactly opposite. In different investigations it is necessary to consider the inclination of the plane of revolution or the plane of the orbit to different planes of reference: the line in which the plane of revolution crosses the plane of reference is called the *line of nodes on that plane*; and the angle which the plane of revolution makes with the plane of reference is called the *inclination to that plane*. The plane of reference must always be supposed to pass through the central body.

(187.) The inclinations of all the orbits, except those of the small planets, are so trifling (the largest—namely, that of the moon's orbit to the earth's orbit—being, at its mean state, only 5°) that they may in general be wholly neglected in estimating the disturbance which one planet produces in the motion of another in its own plane. In some cases, however, as in the inequalities of long period, where the effective force is only the small part which remains after a compensation more or less perfect, no alteration of the forces must be neglected; and here, as we have hinted in (171), the inclinations must be taken into account.

(188.) But though the alteration which the inclination produces in the forces that tend to disturb the body's motion *in* its plane may, in most cases, be neglected, yet the force which tends to pull the body *above* the plane, or *below* the plane, cannot be neglected. In almost every case this force will be less than the force tending to disturb the motion in the plane, yet it will be much greater than the alteration which the inclination produces in that force. It is our object in this section to show the nature of the alteration which is produced by the force tending to pull the body from the plane.

(189.) First, then, as to the effect of a force generally which acts perpendicularly to the plane of revolution. (We shall confine ourselves at present to forces which act perpendicularly to the plane, because it is evident that forces which act in, or parallel to, the plane of the orbit, whether in the radius vector or perpendicularly to it, will not cause the planet to depart from that plane.) Let *fig.* 40 be a perspective representation of an orbit, and a plane of reference. Suppose M A N to be the line of nodes at which the plane of the orbit N B_1 B_2 crosses the plane of reference D E; the central body A being in the line of nodes, and the part of the orbit marked by a dark line being above the plane, and that marked by a dotted line being below it. Suppose that the planet has moved from N to B_1, and that at B_1, before it reached the point highest above the plane D E, a force pulls it down towards the plane. After a short time, instead of going to B_2, where it would have been if no force had disturbed it, it will be found at b_2, having described B_1 b_2, instead of B_1 B_2. It is plain that the orbit in which the planet must have moved without a disturbing force, in order to describe B_1 b_2 now, could not be N B_1, but must be such a curve as *n* B_1, crossing the plane D E at a point in the situation of the point *n*. Therefore, if no more disturbing force acts, the planet, which has described B_1 *b*, as if it came without disturbance from *n*, will go on to describe an orbit as if it had come without disturbance from *n*, and will therefore describe an orbit *n* B_1 b_2 *m*, crossing the plane E F in the points *n* and *m*. The line of nodes is changed from M A N to *m* A *n*.

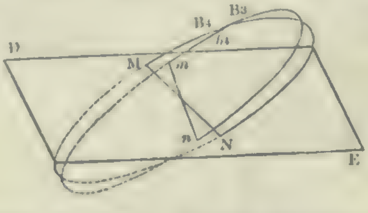
Fig. 40.



(190.) Here the line of nodes has twisted in a direction opposite to the planet's motion, or has *regressed*. The inclination of the new plane is evidently less than that of the old one, since it passes through the same point B, and cuts the plane of reference in a line more distant from B than the line in which the old one cut it, or the inclination is *diminished*.

(191.) Now, if we conceive that at B_3 (*fig.* 41), after the planet has passed the point highest above the plane, a force tends to pull it towards the plane, the planet, instead of going to B_4, will go to b_4, and instead of crossing the plane D E at M, will cross it at *m*; and then, if it is not disturbed again, will proceed in an orbit of which B_3 b_4 *m* is a part, and which will cross the plane D E at the points *m* and *n*. The new line of nodes has twisted here also in the direction opposite to the direction of the planet's motion, or has *regressed*. But the inclination of the new plane is greater than that of the old one, since it passes through the same point B_3, and cuts the plane of reference in a line less distant from B_3 than the line in which the old one cut it, or the inclination is *increased*.

Fig. 41.



(192.) We have, then, this general result: If a force acting perpendicularly to the orbit tends to draw the planet towards the plane of reference, it always causes the line of nodes on that plane to regress: while the planet is moving from a node to the point highest above the plane of reference, it diminishes the inclination to that plane; and while the planet is moving from the highest point to a node, it increases the inclination.

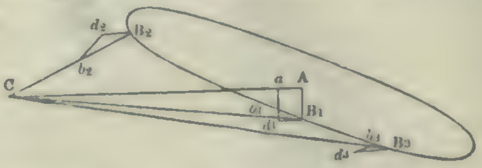
(193.) In the same manner, if the force tends to draw the planet from the plane of reference, it always causes the line of nodes to progress. While the planet is moving from a node to the point highest above the plane, it increases the inclination; and while the planet is moving from the highest point to the node, it diminishes the inclination.

(194.) Similar results would have been obtained if we had considered the action of the force while the planet is in that part of its orbit which is on the other side of the plane D E.

We shall now proceed with the consideration of the force perpendicular to the orbit, which is produced by the attraction of a disturbing body.

(195.) First: it is plain that, if the disturbing body is in the plane of the orbit (produced, if necessary), it will not tend to draw either the central body or the planet out of that plane, and therefore will produce no disturbing force perpendicular to the plane of the orbit. Proceeding, then, with the supposition that the disturbing body is not in the plane of the orbit; and supposing *fig.* 42 to be a perspective view of an orbit B_2 B_1 B_3 (which, to assist our ideas, may be conceived to differ little from a circle) with the disturbing body C out of the plane of the orbit, let us take three points B_1 B_2 B_3, of which B_1 is at the same distance as A from C, B_2 is nearer to C, and B_3 farther from C than A is. Suppose that the attraction of C draws A in a certain small time through the space A *a*, and that when the planet is at B_1, or B_2, or B_3, the attraction draws the planet in the same time through B_1 b_1, or B_2 b_2, or B_3 b_3 respectively. Then (as in (71)) the attraction of C upon the two bodies A and B would produce no disturbance in their relative motions, if it drew them through equal spaces in the same direction. Draw B_1 d_1, B_2 d_2, B_3 d_3 each equal and parallel to A *a*; then if the attraction had drawn B_1 to d_1, there would have been no disturbance, and consequently the real disturbance at B_1 is represented by a force which would have drawn the planet from d_1 to b_1. Similarly, the real disturbances at B_2 and B_3 are represented by forces which would have drawn the planet from d_2 to b_2, and from d_3 to b_3 respectively. Now, since C B_1 is equal to C A, the forces of C upon A and B_1 are equal, and therefore B_1 b_1 is equal to A *a*, and therefore *a* b_1 is parallel to A B_1, and therefore is in the same straight line with b_1 d_1; and consequently at B_1 the whole disturbing force is parallel to the radius vector, and there is no part perpendicular to the plane of the orbit. But at B_2 the planet is nearer to C, the force therefore on the planet is greater, and B_2 b_2 is therefore greater than A *a* or B_2 d_2; also it is more nearly perpendicular to the plane of the orbit than B_2 d_2; and consequently b_2 is farther from the plane of the orbit than d_2; and therefore the disturbing force d_2 b_2 is directed from the plane of the orbit towards the side on which C is. On the contrary, at B_3 the planet is farther from C; the force on the planet is therefore less: and B_3 b_3 is therefore less than A *a* or B_3 d_3; moreover it is inclined more to the perpendicular than B_3 d_3, and consequently b_3 is nearer to the plane of the orbit than d_3; and therefore the disturbing force d_3 b_3 is directed from the side on which C is. Thus we find,

Fig. 42.



(196.) When the central and revolving bodies are equally distant from the disturbing body, there is no disturbing force perpendicular to the plane of the orbit.

(197.) When the revolving body is nearer the disturbing body than the central body is, the disturbing force perpendicular to the plane tends to draw the revolving body out of the plane to that side on which the disturbing body is.

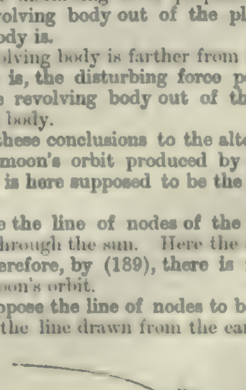
(198.) When the revolving body is farther from the disturbing body than the central body is, the disturbing force perpendicular to the plane tends to draw the revolving body out of the plane to the side opposite the disturbing body.

We may now apply these conclusions to the alteration of the node and inclination of the moon's orbit produced by the sun's attraction. The plane of reference is here supposed to be the plane of the earth's orbit.

(199.) First: suppose the line of nodes of the moon's orbit to be in syzygies, or to pass through the sun. Here the sun is in the moon's orbit produced, and therefore, by (189), there is no disturbing force perpendicular to the moon's orbit.

(200.) Secondly: suppose the line of nodes to be in quadratures, or to be perpendicular to the line drawn from the earth to the sun, as in *fig.* 43. The sun, in the figure, may be considered as being below the plane of the moon's orbit. Also, the moon's distance from the earth being small, the points, at which the moon's distance from the sun is the same as the earth's, are very nearly the same as the points of quadrature, or (in the case before us) they are very nearly the same as

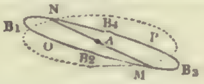
Fig. 43.



the nodes. Consequently, while the moon moves from B_4 through B_1 to B_2, she is nearer to the sun than the earth is, and therefore the disturbing force, by (197), tends to pull her downwards from the plane of her orbit: while the moon moves from B_2, through B_3, to B_4, she is farther from the sun than the earth is, and therefore the disturbing force tends to pull her upwards from the plane of her orbit. In the case before us, then, the disturbing force is always directed towards the plane of reference. Consequently, by (192), while the moon moves from B_4 to B_1, the line of nodes is made to regress, and the inclination is diminished; while the moon moves from B_1 to B_2, the line of nodes regresses, and the inclination is increased; while the moon moves from B_2 to B_3, the line of nodes regresses, and the inclination is diminished: and while the moon moves from B_3 to B_4, the line of nodes regresses, and the inclination is increased. The inclination, therefore, is not sensibly altered in a whole revolution, but the line of nodes regresses during the whole of the revolution.

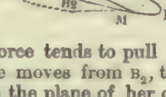
(201.) Thirdly: suppose the line of nodes to be in such a position that the moon passes the line of nodes in going from quadrature to syzygy, as in *fig.* 44. Here the sun is to be considered as below the moon's orbit, and, therefore, while the moon moves from B_4, through B_1, to B_2, the disturbing force tends to pull her down from the plane of the orbit, and while she moves from B_2, through B_3, to B_4, the force tends to pull her up from the plane of her orbit. Therefore, in going from B_4 to N, the force pulls the moon from the plane of reference; and causes thereby a progression of the line of nodes and a diminution of the inclination (193): in going from N to the highest point O, the force pulls the moon towards the plane of reference; and, therefore, causes the nodes to regress, and the inclination to diminish (192); in going from the highest point O to B_2, the force still pulls the moon towards the plane of reference; and, therefore, still causes the nodes to regress, but causes the inclination to increase. Thus while the moon moves from B_4 to N, the force causes the line of nodes to progress, and while she moves from N to B_2, it causes the line of nodes to regress; and, similarly, while she moves from B_2 to M, the force causes the line of nodes to progress; and while she moves from M to B_4, it causes the line of nodes to regress. On the whole, therefore, the line of nodes regresses, but not so rapidly as in the second case. Also, while the moon moves from B_4 to O the inclination is diminished, and while she moves from O to B_2 the inclination is increased; and, similarly, while she moves from B_2 to P the inclination is diminished; and while she moves from P to B_4 the inclination is increased. On the whole, therefore, the inclination is diminished.

Fig. 44.



(202.) Fourthly: suppose the line of nodes to be in such a position that the moon passes it in going from syzygy to quadrature, as in *fig.* 45. Here, also, the sun is below the plane of the orbit produced; and, therefore, from B_4 to B_2 the force tends to pull the moon down from her orbit; and from B_2 to B_4 it tends to pull her up from it. As in the last case it would be seen, that while the moon moves from B_4 to M, the line of nodes regresses; while from M to B_2, the line of nodes progresses; while from B_2 to N, the line of nodes regresses; and while from N to B_4, the line of nodes progresses. On the whole, therefore, the line of nodes regresses. Also, it will be seen, that while the moon moves from B_4 to O, the inclination is diminished; while from O to B_2, the inclination is increased; while from B_2 to P, the inclination is diminished; and while from P to B_4, the inclination is increased. On the whole, therefore, the inclination is increased.

Fig. 45.



The same reasoning would apply, and lead to the same conclusions in every respect, if we supposed the moon's orbit inclined in the opposite direction.

(203.) Now the earth moves round the sun, and, therefore, the sun appears to move round the earth, and in the same direction in which the moon moves round the earth. If then we begin with the state in which the line of nodes is passing through the sun (and in which neither the node nor the inclination undergoes any change, by the first case), we come next to the state in which the moon passes the line of nodes in going from quadrature to syzygy (in which the node regresses and the inclination diminishes, by the third case); then we come to the state in which the line of nodes coincides with the line of quadratures (in which the node regresses rapidly, and the inclination is not altered, by the second case); then we come to the state in which the moon passes the line of nodes in going from syzygy to quadrature (in which the node regresses and the inclination is increased, by the fourth case); and then we come to the state in which the line of nodes again passes through the sun. This is when the sun has described, apparently, half a revolution round the earth (or rather less, in consequence of the regression of the node), and in the other half revolution, the same changes in every respect take place in the same order. The inclination, therefore, is greatest when the line of nodes passes through the sun, or coincides with the line of syzygy; and is least when the line of nodes coincides with the line of quadratures; since it is constantly diminishing while we are going from the former state to the latter, and constantly increasing while we are going from the latter state to the former. This is the principal irregularity in the inclination of the moon's orbit; all the others are very small.

(204.) The line of nodes is constantly regressing at every revolution of the moon, except when the line of nodes passes through the sun. The annual motion which we might at first expect it to have is somewhat diminished by the circumstance that the rapid regression of the line of nodes, when in the position in which the greatest effect is produced, carries it from the line of quadratures more swiftly than the sun's progressive motion only, by making the line of quadratures to progress, would separate them. But as the line of nodes never progresses, the diminution of the motion of the line of nodes thus occasioned is very much less than the increase of the motion of the line of apses (107). Also, as the force acting on opposite points of the orbit tends to produce effects of the same kind, there is no irregularity similar to that explained in (106). Hence the actual regression of the line of nodes, though a little less than might at first be expected, differs from that regression by a much smaller quantity than that by which the actual motion of the line of apses differs from the motion which at first we might expect it to have. The line of nodes revolves completely round in something more than nineteen years.

(205.) The effect of the irregularity in the regression of the nodes, and the effect of the alternate increase and diminution of the inclination, are blended into one inequality of latitude, which depends on the sun's longitude, the longitude of the moon's node, and the moon's longitude. This inequality was discovered (from observation) by Tycho Brahé, about 1590. It may be considered to bear the same relation to the inclination which the evection bears to the excentricity; and, like the evection in longitude, it is the greatest of the inequalities in latitude. It is, however, much less than the evection; its greatest effect on the moon's latitude being about 8′, by which the mean inclination is sometimes increased and sometimes diminished.

(206.) There are other small inequalities in the moon's latitude, arising partly from the changes in the node and inclination, which take place several times in the course of each revolution (200), &c.; partly from the excentricity of the orbits of the moon and the earth, partly from the distortion accompanying the *variation*, and partly from the variability of the inclination itself. We shall not, however, delay ourselves with the explanation of all these terms.

(207.) We shall now proceed with the disturbance of the planets in latitude.

In this inquiry it is always best to take the orbit of the disturbing planet for the place of reference. Now let us first consider the case of Mercury or Venus disturbed by Jupiter. In this case Jupiter revolving in a long time round the sun, which is the central body to Mercury or Venus, produces exactly the same effect as the sun revolving (or appearing to revolve) round the earth, which is the central body to the moon. The disturbing force of Jupiter therefore produces a regression of the nodes of the orbits of Mercury and Venus on Jupiter's orbit; and an irregularity in the motion of each node, and an alteration in the inclination, whose effects might be combined into one: and this is the only inequality in their latitude, produced by Jupiter, whose effects are sensible.

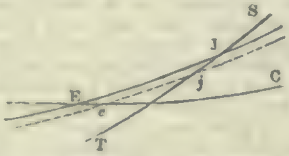
(208.) The other inequalities in latitude, depending on the relative position of the planets, possess no particular interest; and a general notion of them may be formed from the remarks in the discussion of the motion of the moon's node. One case, however, may be easily understood. When an exterior planet is disturbed by the attraction of an interior one, whose distance from the sun is less than half the distance of the exterior planet, and whose periodic time is much shorter, then the exterior planet is always further from the interior planet than the sun is; and therefore, by (195), there is a disturbing force urging it from the plane of reference when the planets are in conjunction, and to it when they are in opposition; and thus the exterior planet is pushed up and down for every conjunction of the two planets. The disturbance, however, is nothing when the exterior planet is at the line of its nodes (195).

(209.) The near commensurability of periodic times, which so strikingly affects the major axis, the excentricity and the place of perihelion, produces also considerable effects on the node and the inclination. The reasoning of (175) and (176) will in every respect apply to this case; the greatest effect is produced, both on the motion of the node and on the change of inclination, when the planets are in conjunction: the gradual alteration of the point of conjunction produces a gradual alteration of these effects, which, however (in such a case as that of Jupiter and Saturn), is partially counteracted by the gradual change of the other points of conjunction: the uncompensated part, however, may, in many years, produce a very sensible irregularity in the elements. If we put the words *line of nodes* for *line of apses*, and *inclination* for *excentricity*, the whole of the reasoning in (175), &c., will apply almost without alteration.

(210.) For the secular variation of the position of the orbit, the following considerations seem sufficient. In the long run the disturbed planet has been at every one point of its orbit a great number of times, while the disturbing planet has been at almost every part of its orbit. The disturbing force is always the difference of the forces which act on the sun and on the disturbed planet. As the disturbing planet, in these various positions, acts upon the sun in all directions in the plane of its orbit, its effect on the sun may be wholly neglected; and then it is easy to see that, whether the disturbing planet be exterior or interior to the other, the combined effect of the forces in all these points on the disturbed planet at one point is to pull it from its orbit towards the plane of the disturbing planet's orbit. (This depends upon the circumstance that the force is greatest when the disturbing planet is nearest.) Consequently, by (192), the line of nodes of the disturbed planet's orbit on the disturbing planet's orbit, in the long run, always regresses. If the orbits are circular, there is no alteration of the inclination, since, at points equally distant from the highest point, there is the same force on the disturbed planet; and, therefore, by (192), the inclination is increased at one time, and diminished as much at another. If the orbits are elliptic, one point may be found where the effect of the force on the inclination is greater than at any other, and the whole effect on the inclination will be similar to that.

(211.) In stating that the nodes always regress in the long run, the reader must be careful to restrict this expression to the sense of regressing on the orbit of the disturbing planet. It may happen that on another orbit they will appear to progress. Thus the nodes of Jupiter's orbit are made to regress on Saturn's orbit by Saturn's disturbing force. The nodes of these orbits on the earth's orbit are not very widely separated; but the inclination of Saturn's orbit is greater than that of Jupiter's. If we trace these on a celestial globe, we shall have such a figure as *fig.* 46, where E C represents the plane of the earth's orbit, J E the orbit of Jupiter, and S T that of Saturn. The orbit of Jupiter, by regressing on Saturn's orbit, assumes the position of the dotted line *j e*; but it is plain that the intersection of this orbit with the earth's orbit has gone in the opposite direction, or has progressed. If the motion of the node on Saturn's orbit from J to *j* is regression, the motion of the node on the earth's orbit from E to *e* must be progression.

Fig. 46.



(212.) There is a remarkable relation between the inclinations of all the orbits of the planetary system to a fixed plane, existing through all their secular variations, similar to that between their excentricities. The sum of the products of each mass, by the square root of the major axis of its orbit, and by the square of the inclination to a fixed plane, is invariable.

(213.) The disturbance of Jupiter's satellites in latitude presents circumstances not less worthy of remark than the disturbance in longitude. The masses are so small, and their orbits so little inclined to each other, that the small inequalities produced in a revolution may be neglected. Even that depending on the slow revolution of the line of conjunctions of the first three satellites, so small is the mutual inclination of their orbits, does not amount to a sensible quantity. We shall therefore consider only those alterations in the position of the planes of the orbits which do not vary sensibly in a small number of revolutions. For this purpose we must introduce a term which has not been introduced before.

(214.) If the moon revolved round the earth in the same plane in which the earth revolves round the sun, the sun's attraction would never tend to draw the moon out of that plane. But (taking the circumstances as they really exist) the moon revolves round the earth in a plane inclined to the plane in which the earth revolves round the sun; and the consequence, as we have seen is, that the line of nodes upon the latter plane regresses, and the inclination of the orbit to the latter plane remains, on the whole, unaltered. The plane of the earth's orbit, then, may be considered a *fundamental plane* to the moon's motion; by which term we mean to express, that if the moon moved in that plane, the disturbing force would never draw her out of it; and that if she moved in an orbit inclined to it, the orbit would always be inclined at nearly the same angle to that plane, though its line of nodes had sensibly altered. The latter condition will, in general, be a consequence of the former.

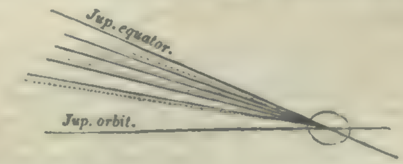
(215.) In order to discover what will be the fundamental plane for one of Jupiter's satellites, we must consider that, besides the sun's attraction, there is another and more powerful disturbing force acting on these bodies, namely, the irregularity of attraction produced by Jupiter's flatness. The effect of this (as we shall show) is always to pull the satellites towards the plane of Jupiter's equator. If Jupiter were spherical, the only disturbing force would be the sun's attraction, tending on the whole to draw the satellite towards the plane of Jupiter's orbit, and that plane would be the fundamental plane of the satellite. If Jupiter were flattened, and if the sun did not disturb the satellite, the irregularity in Jupiter's shape would always tend to draw the satellite towards the plane of his equator, and the plane of his equator would be the fundamental plane of the satellite. As both causes exist, the position of the actual fundamental plane must be found by the following consideration. We must discover the position of a plane from which the sun's disturbing force tends, on the whole, to draw the satellite downwards, and the disturbing force depending upon Jupiter's shape tends to draw it upwards (or *vice versâ*), by equal quantities; and that plane will be the fundamental plane. This plane must lie *between* the planes of Jupiter's orbit and Jupiter's equator, because thus only can the disturbing forces act in opposite ways, and therefore balance each other: and it must pass through their intersection, as otherwise it would at that part be above both or below both, and the forces depending on both causes would act the same way.

(216.) The disturbing force of the sun, as we have seen (82), &c., is greater as the satellite is more distant; the disturbing force depending on Jupiter's shape is then less, as we shall mention hereafter. Consequently, as the satellite is more distant, the effect of the sun's disturbing force is much greater in proportion to that depending on Jupiter's shape. Thus, if there were a single satellite at the distance of Jupiter's first satellite, its fundamental plane would nearly coincide with the plane of Jupiter's equator; if at the distance of Jupiter's second satellite, its fundamental plane would depart a little farther from coincidence with the plane of the equator; and so on for other distances; and if the distance were very great, it would nearly coincide with the plane of Jupiter's orbit. If, then, Jupiter's four satellites did not disturb each other, each of them would have a separate fundamental plane, and the positions of these planes would depend only upon each satellite's distance from Jupiter.

(217.) In fact, the satellites do disturb each other. In speaking of the planets (210), we have observed that the effect of the attraction of one planet upon another, in the long run, is to exert a disturbing force tending to draw that other planet (at any part of its orbit) towards the plane of the first planet's orbit. The same thing is true of Jupiter's satellites. Now, though each of them moves generally in an orbit inclined to its fundamental plane, yet in the long run (when the nodes of the orbit have regressed many times round), we may consider the motion of each satellite as taking place in its fundamental plane. The question, therefore, must now be stated thus. The four satellites are revolving in four different fundamental planes; and the position of each of these planes is to be determined by the consideration that the satellite in that plane is drawn towards the plane of Jupiter's orbit by the sun's disturbing force, towards the plane of Jupiter's equator by the force depending on Jupiter's shape, and towards the plane of each of the other three satellites, by the disturbing force produced by each satellite: and these forces must balance in the long run.

(218.) The determination of these planes is not very difficult, when general algebraical expressions have been investigated for the magnitude of each of the forces. The general nature of the results will be easily seen; the several fundamental planes will be drawn nearer together (that of the first satellite, that of the second, and that of the third, will be drawn nearer to Jupiter's orbit, while that of the fourth will be drawn nearer to Jupiter's equator). The four planes will still pass through the intersection of the plane of Jupiter's equator with that of Jupiter's orbit. Thus, if we conceive the eye to be placed at a great distance, in the intersection of the planes of Jupiter's orbit and Jupiter's equator, and if the dotted lines in *fig.* 47 represent the appearance of the fundamental planes which would exist if the satellites did not disturb each other, then the dark lines will represent the positions of these planes as affected by the mutual disturbances. The inclination of Jupiter's equator to Jupiter's orbit is about $3^\circ\ 5'$; and so great is the effect of his shape, that the fundamental plane of the first satellite is inclined to his equator by only $7''$; that of the second satellite by about $1'$; that of the third by about $5'$; and that of the fourth by about $24\frac{1}{2}'$. Without mutual perturbation, the inclinations to Jupiter's equator would have been about $2''$, $20''$, $4'$, and $48'$.

Fig. 47.



(219.) Having considered the positions of the fundamental planes, we shall now consider the motion of a satellite, when moving in an orbit inclined to its fundamental plane.

(220.) The general effect will be of the same kind as that for the moon. Since the disturbing force which then tends to pull it from the plane of its orbit, tends to pull it towards the fundamental plane (as, supposing the satellite to be on that side of the fundamental plane next the plane of Jupiter's equator, the sun's disturbing force towards Jupiter's orbit is increased, that towards Jupiter's equator is diminished, and so for the others), the line of nodes will regress on the fundamental plane. The inclination on the whole will not be altered. That part of the regression of the nodes which depends on the sun's disturbing force will be greater for the distant satellites than for the near ones; but that which depends on the shape of Jupiter (and which is much more important) will be greater for the near satellites than for the distant ones. On the whole, therefore, the lines of nodes of the interior satellites will regress more rapidly than those of the exterior ones. Their annual regressions (beginning with the second) are, in fact, 12°, 2°, 32′, and 41′.

(221.) But the disturbing force of one satellite upon the others will be altered by the circumstance of its orbit not coinciding with its fundamental plane; and the orbit remains long enough in nearly the same position to produce a very sensible irregularity. To discover the nature of this, we must observe that the force of one satellite, perpendicular to the orbit of another, depends wholly upon the inclination of the two orbits, so that, upon increasing the inclination, the disturbing force is affected. Suppose now, to fix our ideas, the second satellite moves in an orbit inclined to its fundamental plane; what is the kind of disturbance that it will produce in the latitude of the first satellite? First, it must be observed, that when moving in the fundamental planes, the forces depending upon the inclination of those planes were taken into account in determining the position of those planes: so that here we have to consider only the alteration produced by the alteration in the second satellite's place. Next we shall proceed in the same manner as in several preceding instances, by finding what is the motion of the first satellite, related to the motion of the second satellite, which can exist permanently with this inclination of the second satellite. Now, in whatever part the actual orbit of the second is higher above, or less depressed below, the orbit of the first, than the fundamental plane of the second was, at that part there will be a greater force drawing the first satellite up, or a smaller force drawing it down (in the conjunctions at that part), than before. The alteration of force, then, will be generally represented by supposing a force to act on the first satellite, at different points of its orbit, towards the same side of its orbit as the side on which the second satellite's orbit is there removed from its fundamental plane, and proportional to the magnitude of that removal. Now, conceiving the inequality introduced into the motion of the first satellite to be a small inclination of its orbit to its fundamental plane (which is the only inequality of Jupiter's satellites that we consider), the nodes of this orbit cannot correspond to the places where the second satellite is furthest from its fundamental plane; for then, at one node of the first satellite, the disturbing force, before and after passing that node, being great, and not changing its direction, would not alter the place of the node, but would greatly alter the inclination: and at the opposite node, the force acting in the opposite direction would produce the same effect; and thus the permanency of the inequality would be destroyed. We must then suppose the nodes of the orbit of the first satellite on its fundamental plane to coincide with those of the orbit of the second satellite on its fundamental plane. But is the inclination to be the same way, or the opposite way? To answer this, we must consider that the action of Jupiter's shape would tend to make the nodes of the first satellite regress much more rapidly than those of the second; but as our orbit of the first satellite is assumed to accompany the second in its revolution, the disturbing force depending on the second must be such as to destroy a part of this regression, or to produce (separately) a progression of the nodes of the first; consequently, the disturbing force produced by the second must tend to draw the first from its fundamental plane (193). But the disturbing force produced by the second is in the same direction as the distance of the second from the fundamental plane of the second; consequently, the orbit of the first must lie in the same position, with regard to the fundamental plane of the first, in which the orbit of the second lies with regard to the fundamental plane of the second. The same reasoning applies to every other case of an interior satellite disturbed by an exterior; and thus we have the conclusion: If the orbit of one of Jupiter's satellites is inclined to its fundamental plane, it affects the orbit of each of the satellites interior to it with an inclination of the same kind, and with the same nodes.

(222.) Let us now inquire what will be the nature of the inequality produced in the latitude of the third satellite. The same reasoning and the same words may, in every part, be adopted, except that the regression of the nodes of the third satellite, as produced by Jupiter's shape, will be slower than that of the second satellite, and therefore the disturbing force which acts on the third must now be such as to quicken the regression of its nodes, and must therefore be directed towards its fundamental plane. From this consideration we find, as a general conclusion, if the orbit of one of Jupiter's satellites is inclined to its fundamental plane, it affects the orbit of each of the satellites exterior to it, with an inclination of the opposite kind, but with the same nodes.

(223.) The first satellite's orbit appears to have no sensible inclination to its fundamental plane; but those of the second, third, and fourth, are inclined to their fundamental planes (the second 25′, and the third and fourth about 12′), and these are found to produce in the others inequalities such as we have investigated.

(224.) It is only necessary to add, that the disturbance of the first satellite by the second produces an alteration in the action of the first on the second, tending to draw the second from its fundamental plane, and therefore to diminish, by a small quantity, the regression of its nodes. In the same manner, the altered action of the third on the second tends to draw the second towards its fundamental plane, and therefore to increase, by a small quantity, the regression of its nodes. There is exactly the same kind of complication with regard to the disturbances of these bodies in latitude as with regard to those in longitude, explained in (150), &c.

(225.) The only other inequality in latitude, which is sensible, is that depending on the position of the sun, with regard to the nodes of the orbits on the plane of Jupiter's orbit (that is, with regard to the node of Jupiter's equator on Jupiter's orbit), and this amounts to only a few seconds. It is exactly analogous to that of the moon, explained in (205).

SECTION IX.—*Effects of the Oblateness of Planets upon the Motions of their Satellites.*

(226.) In the investigations of motion about a central body, we have supposed that central body to be a spherical ball. This makes the investigation remarkably simple; for it is demonstrated by mathematicians, that the spherical form possesses the following property: the attraction of all the matter in a sphere upon another body at any distance external to it is exactly the same as if all the matter of the sphere were collected at the centre of the sphere. In the investigation of motion about a centre we may therefore lay aside (as we have usually done) all consideration of the size of the attracting body, if that body is spherical.

(227.) But the planets are not spherical. Whether or not they have ever been fluid, still they have (at least, the earth has) a great extent of fluid on its surface, and the form of this fluid will be affected by the rotation of the planet. The fluid will spread out most where the whirling motion is most rapid, that is, at the equator. Thus it appears from theory, and it is also found from measures, that the earth is not a sphere, but a spheroid, flattened at the north and south poles, and protuberant at the equator. The proportion of the axes differs little from the proportion of 299 : 300; so that a line drawn through the earth's centre, and passing through the equator, is longer than one passing through the poles, by 27 miles.

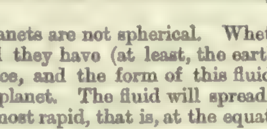
(228.) The flattening of Jupiter is still more remarkable. The proportion of his axes differs little from that of 13 : 14, and thus the difference of his diameters is nearly 6000 miles. In fact, the eye is caught by the elliptic appearance of Jupiter, on viewing him for a moment in a telescope.

(229.) It is our business, in the present section, to point out the general effects of this shape upon the motion of satellites. The agreement of observation with calculation on this point is certainly one of the most striking proofs of the correctness of the theory, "that every particle of matter attracts every other particle, according to the law of Universal Gravitation."

(230.) We will begin with explaining the law according to which an oblate planet attracts a satellite in the plane of its equator.

The spheroid represented by the dark line in *fig.* 48 may be supposed to be formed from the sphere represented by the dotted line, by cutting off a quantity of matter from each pole. To simplify our conception, let us suppose that all the matter cut off was in one lump at each pole; that is, at the points D and E. The attraction of the whole sphere on the satellite B, as we have remarked, is the same as if all the matter of the sphere were collected at A. But the attraction of the part cut off is not the same as if it were collected at A, inasmuch as its distance from B is greater, and as the direction of the attraction to D, or to E, is not the same as that to A. Thus, suppose A D is called 1, and A B is called 10. Since the forces are inversely as the squares of the distances at which the attracting mass is situate, the attraction of the lump D, if at the point A, where its distance from B is 10, may be called $\frac{1}{100}$; but if at D, it must be called $\frac{1}{101}$, since the square of B D is equal to the sum of the squares of B A and A D, that is, to the sum of 100 and 1. Also the direction of attraction is not the same; for, if the attraction of D should draw the satellite through B b, and if b c be drawn perpendicular to A B, the only effective approach to A is the distance B c, which is less than B b in the proportion of B A to B D, or of 10 to $\sqrt{101}$; and, therefore, the effective attraction of D, estimated by the space through which it draws the satellite towards A must be called $\frac{10}{101 \times \sqrt{101}}$. And this is the whole effect which its attraction produces; for though the attraction of D alone tends to draw the satellite above A B, yet the attraction of E will tend to draw it as much below A B; and thus the parts of the force which act perpendicular to A B will destroy each other. We have, then: the attraction of the lump D, if placed at A, would be represented by $\frac{1}{100} = 0{\cdot}01$; but as placed as D, its effective attraction is represented by $\frac{10}{101 \times \sqrt{101}} = 0{\cdot}0098518$. The difference is 0·0001482, or nearly $\frac{1500}{100000}$th of the whole attraction of D, and the same for E. Consequently, the lumps at D and E produce a smaller

Fig. 48.



effective attraction on B than if they were collected at A; but the whole sphere produces the same effect as if its whole mass were collected at A; and, therefore, the part left after cutting away the lumps at D and E produces a greater attraction than if its whole mass were collected at A.

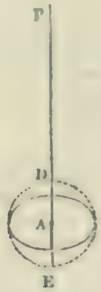
(231.) But it is important to inquire, whether this attraction is greater than if the matter of the spheroid were collected at the centre, in the same proportion at all distances of the satellite. For this purpose, suppose the distance of the satellite to be 20. The same reasoning would show, that the attraction of the lump D, if placed at A, must now be represented by $\frac{1}{400} = 0{\cdot}0025$; but that, if placed at D, its effective attraction is represented by $\frac{20}{401 \times \sqrt{401}} = 0{\cdot}002490653$. The difference now is 0·000009347, or nearly $\frac{375}{100000}$ of the whole attraction of D. Consequently by removing the satellite to twice the distance from A, the difference between the effective attraction of the lump at A and at D bears to the whole attraction of the lump at A a proportion four times smaller than before. And, therefore, the attraction of the spheroid, though still greater than if its whole matter were collected at A, differs from that by a quantity, whose proportion to the whole attraction is only one-fourth of what it was before. If we tried different distances in the same manner, we should find, as a general law, that the proportion which the difference (of the actual attraction, and the attraction supposing all the matter collected at the centre) bears to the latter, diminishes as the square of the distance from A increases.

(232). The attraction of an oblate spheroid upon a satellite, or other body, in the plane of its equator, may therefore, be stated thus:—There is the same force as if all the matter of the spheroid were collected at its centre, and, besides this, there is an additional force depending upon the oblateness, whose proportion to the other force diminishes as the square of the distance of the satellite is increased.

(233.) Now, let us investigate the law according to which an oblate spheroid attracts a body, situate in the direction of its axis.

Proceeding in the same manner as before, and supposing the distance A B to be 10, the attraction of the lump, which at A would be represented by $\frac{1}{100}$, will at D be represented by $\frac{1}{81}$, and will at E be represented by $\frac{1}{121}$, (since the distances of D and E from B are respectively 9 and 11). Hence, if the two equal lumps, D and E, were collected at the centre, their attraction on B would be $\frac{1}{100}+\frac{1}{100}=\frac{1}{50} = 0{\cdot}02$. In the positions D and E the sum of their attractions on B is $\frac{1}{81}+\frac{1}{121} = 0{\cdot}0206100$. The difference is 0·0006100, by which the attraction in the latter case is the greater. Consequently, the attraction of the lumps in the positions D and E is greater than if they were collected at the centre by nearly $\frac{3}{10}$ths of their whole attraction; but the attraction of the whole sphere is the same as if all the matter of the sphere were collected at the centre; therefore, when these parts are removed, they must leave a mass, whose attraction is less than if its whole matter were collected in the centre. With regard to the alteration depending on the distance of B, it would be found, on trial, to follow the same law as before.

Fig. 49.



(234). The attraction of a spheroid on a body in the direction of its axis may, therefore, be represented, by supposing the whole matter collected at the centre, and then supposing the attraction to be diminished by a force depending on the oblateness, whose proportion to the whole force diminishes as the square of the distance of the body is increased.

(235). Since the attraction on a body, in the plane of the equator, is greater than if the mass of the spheroid were collected at its centre, and the attraction on a body in the direction of the axis is less, it will readily be understood, that in taking directions, successively more and more inclined to the equator, on both sides, the attraction successively diminishes. And there is one inclination, at which the attraction is exactly the same as if the whole mass of the spheroid were collected at its centre.

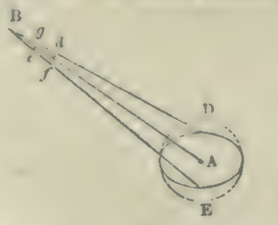
(236). Now, suppose that a satellite revolves in an orbit, which coincides with the plane of the equator, or makes a small angle with it; what will be the nature of its orbit? For this investigation we have only to consider, that there is acting upon the satellite a force, the same as if all the matter of the spheroid were collected at its centre, and, consequently, proportional inversely to the square of the distance, and that, with this force only, the satellite would move in an ellipse, whose focus coincided with the centre of the spheroid. But besides this, there is a force always directed to the centre, depending on the oblateness. One effect of it will be, that the periodic time will be shorter with the same mean distance, or the mean distance greater with the same periodic time, than if the former were the only force. (46). Another effect will be, that when the satellite is at its greatest distance, this force will cause the line of apses to regress, and when at its smallest distance, this force will cause the line of apses to progress, (50) and (53). If this force, at different distances, were in the same proportion as the other attractive force, it would, on the whole, cause no alteration in the position of the line of apses, (for it would amount to the same as increasing the central mass in a certain proportion, in which case an ellipse, with invariable line of apses, would be described; that is, the regression at the greatest distance would be equal to the progression at the least distance. (*See the note to* (98).) But (231) the proportion of this force to the other diminishes as the distance is increased. Consequently, the regression at the greatest distance is less than the progression at the least distance, and, therefore, on the whole, the line of apses progresses. Also, the nearer the satellite is to the planet, the greater is the proportion of this force to the other attraction; and, therefore the more rapid is the progression of the line of apses at every revolution. The progression of the line of apses of the moon's orbit, produced by the earth's oblateness, is so small in comparison with that produced by the sun's disturbing force, that it can hardly be discovered; but the progression of the line of apses in the orbits of Jupiter's satellites, produced by the oblateness of Jupiter, is so rapid, especially for the nearest satellites, that the part produced by the sun's disturbing force is small in comparison with it.

(237.) We shall now proceed with the investigation of the disturbance in a satellite's latitude, produced by the oblateness of a planet.

(238.) First, It is evident that if the satellite's orbit coincides with the plane of the planet's equator, there will be no force tending to pull it up or down from that plane; and, therefore, it will continue to revolve in that plane. In this case, then, there is no disturbance in latitude; we must, therefore, in the following investigation, suppose the orbit inclined to the plane of the equator.

In *fig.* 50, then, let us consider (as before) the effect of the attractions of the two lumps at D and E, in pulling the satellite B perpendicularly to the line A B. Now D is nearer to B than E is; also the line D B is more inclined than E B to A B. If the attraction of D alone acted, it would in a certain time draw the satellite to *d*; and *f d* would be the part of the motion of B, which is perpendicular to A B; and this motion is upwards. In like manner, if the attraction of E alone drew B to *e* in the same time, *g e* would be the motion perpendicular to A B, and this motion is downwards. When both attractions act, these effects are combined; the question then is, which is greater, *f d* or *g e*? Now, since D is nearer than E, the attraction of D is greater than that of E, therefore B *d* is greater than B *e*; also B *d* is more inclined than B *e* to B A; therefore *d f* is much greater than *g e*. Hence, the force which tends to draw B upwards is the preponderating force; and therefore, on the whole, the combined attractions of D and E will tend to draw the satellite upwards from the line B A. But the attraction of the whole sphere would tend to draw it along the line B A. Therefore, when D and E are removed, the attraction of the remaining mass (that is, the oblate spheroid) will tend to draw B below the line B A. In estimating the attraction of an oblate spheroid, therefore, we must consider, that besides the force directed to the centre of the spheroid, there is always a force perpendicular to the radius vector directed towards the plane of the equator, or tending to draw a satellite from the plane of its orbit towards the plane of the planet's equator. If the satellite is near to the planet, the inequality of the proportion of the distances D B and E B is increased, and the inequality of the inclinations to B A is also increased; and the disturbance is, therefore, much greater for a near satellite than for a distant one.

Fig. 50.



(239.) We have seen (215) the effect of this disturbing force in determining the fundamental planes of the orbits of Jupiter's satellites. And from (192), &c., we can infer, at once, that this force will cause the line of nodes to regress, if the orbit is inclined to the fundamental plane, and the more rapidly as the satellite is nearer to the planet. If there were no other disturbing force, the inclination of those orbits to the plane of Jupiter's equator would be invariable, and their nodes would regress with different velocities, those of the near satellites regressing the quicker. In point of fact, the circumstances of the inner satellites are very nearly the same as if no other disturbing force existed, so great is the effect produced by Jupiter's oblateness.

(240.) The figure of Saturn, including in our consideration the ring which surrounds him, is different from that of Jupiter; but the same principles will apply to the general explanation of its effects on the motion of its satellites. The body of Saturn is oblate, and the forces which it produces are exactly similar to those produced by Jupiter. The effect of the ring may be thus conceived:—If we inscribe a spherical surface in an oblate spheroid, touching its surface at the two poles, the spheroid will be divided into two parts; a sphere whose attraction is the same as if all its matter were collected at its centre, and an equatorial protuberance analogous in form to a ring. The whole irregularity in the attraction of the spheroid is evidently due to the attraction of this ring-like protuberance, since there is no such irregularity in the attraction of the sphere. We infer therefore that the irregularity in the attraction of a ring is of the same kind as the irregularity in the attraction of a spheroid, but that it bears a much greater proportion to the whole attraction for the ring than for the spheroid, since the ring produces all the irregularity without the whole attraction. Now, the plane of Saturn's ring coincides with the plane of Saturn's equator, so that the effect of the body and ring together is found by simply adding effects of the same kind, and is the same as if Saturn were very oblate. The rate of progression of the perisaturnium of any satellite, and the rate of regression of its node, will therefore be rapid. In other respects it is probable that the theory of these satellites would be very simple, since all (except the sixth) appear to be very small, and the sun's disturbing force is too small to produce any sensible effects.

(241.) The satellites of Saturn, except the sixth, have been observed so little that no materials exist upon which a theory can be founded. A careful series of observations on the sixth satellite has lately been made by Bessel, from which, by comparing the observed progress of the perisaturnium and regression of the node with those calculated on an assumed mass of the ring, the real mass of the ring has been found. It appears, thus, that the mass of the ring (supposing the whole effect due to the ring) is about $\frac{1}{11}$th of the mass of the planet.

(242.) The effect of the earth's oblateness in increasing the rapidity of regression of the moon's nodes is so small, that it cannot be discovered from observation. But the effect on the position of the fundamental plane is discoverable. We have seen (204) that the moon's line of nodes regresses completely round in 19½ years. The plane of the earth's equator is inclined 23½° to the earth's orbit, and the line of intersection alters very slowly. At some time therefore the line of nodes coincides with the intersection of the plane of the earth's equator and the plane of the earth's orbit, so that the plane of the moon's orbit lies between those two planes; and 9¾ years later, the line of nodes again coincides with the same line, but the orbit is inclined the other way, so that the plane of the moon's orbit is more inclined than the plane of the earth's orbit to the plane of the earth's equator. Now it is found that in the former case the inclination of the moon's orbit to the earth's orbit is greater than in the latter by about 16", and this shows that the plane to which the inclination has been uniform is neither the plane of the earth's equator nor that of the earth's orbit, but makes with the latter an angle of about 8", and is inclined towards the former.

(243.) There is another effect of the earth's oblateness (the only other effect on the moon which is sensible) that deserves notice. The inclination of the moon's orbit to the earth's orbit is less than 5°, and the inclination of the earth's equator to the earth's orbit is 23½°. Consequently, when the moon's orbit lies between these two planes, the inclination of the moon's orbit to the earth's equator is about 19°; and when the line of nodes is again in the same position, but the orbit is inclined the other way, the inclination of the moon's orbit to the earth's equator is about 28°. At the latter time, therefore, in consequence of the earth's oblateness, the moon, when farthest from its node, will, by (235), experience a smaller attraction to the earth than at the former time when farthest from its node. When in the line of nodes, the attractions in the two cases will be equal. On the whole therefore the attraction to the earth will be less at the latter time than at the former. For the period of 9¾ years therefore the earth's attraction on the moon is gradually diminished, and then is gradually increased for the same time. The moon's orbit (47) becomes gradually larger in the first of these times, and smaller in the second. The change is very minute, but, as explained in (49) the alteration in the longitude may be sensible. It is found by observation to amount to about 8", by which the moon is sometimes before her mean place, and sometimes behind it. If the earth's flattening at each pole were more or less than $\frac{1}{300}$th of the semi-diameter, the effects on the moon, both in altering the position of the fundamental plane, and in producing this inequality in the longitude, would be greater or less than the quantities that we have mentioned; and thus we are led to the very remarkable conclusion, that by observing the moon we can discover the amount of the earth's oblateness, supposing the theory to be true. This has been done; and the agreement of the result thus obtained, with that obtained from direct measures of the earth, is one of the most striking proofs of the correctness of the Theory of Universal Gravitation.

GRAVITY, CENTRE OF, is that point at which all the weight of a mass might be collected without disturbing the equilibrium of any system of which the mass forms a part. Thus, if a lever were balanced by means of two solid spheres of uniform density hung at the ends, the equilibrium would still remain if all the matter of either of the spheres could be concentrated at its centre. The centre of the sphere is then its centre of gravity.

When a body is suspended by a string, and allowed to find its position of rest, the centre of gravity is in the line of continuation of the string. If then a body be suspended successively at two different points, and if the lines in which the strings produced would cut through the body can be conveniently determined, the centre of gravity is the point of intersection of the two lines. This process is very easy in the case of a thin flat surface, and the approximation is quite sufficient for practical purposes.

When a surface (or a thin plate) is of uniform density, the centres of gravity and of figure [Centre] are the same. It is needless to say where this falls in the case of a circle, of a square or other parallelogram, or of a regular oval figure. In a triangle it is found by joining the vertex and middle of the base, and cutting the intercepted line into three equal parts, the nearest trisecting point to the base giving the centre of gravity. In a prism and cylinder it is the middle point of the line joining the centres of gravity of the two bases. In a cone or pyramid it is found by joining the vertex and the centre of gravity of the base, and cutting the joining line into four equal parts, the nearest of which to the base ends in the centre of gravity. In a semicircle the distance of the centre of gravity from the centre is about fourteen thirty-thirds of the radius; in a hemisphere this same distance is five-eighths of the radius.

The centre of gravity of two bodies is found by joining their centres of gravity, and dividing the joining line so that the content of the first may be to that of the second as the segment adjoining the second is to that adjoining the first. By the same rule, and by the centre of two bodies thus found and that of a third, the centre of three bodies may be found, taking care to use with each centre the sum of all the contents of the bodies employed in finding it.

GRAVITY, SPECIFIC. [Specific Gravity.]

GREAT CIRCLE or TANGENT SAILING. Although the subject will be found properly introduced under the general head Navigation, the peculiar nature of Great Circle Sailing, and its growing importance to underwriters, shipowners, and therefore to the whole mercantile interests of Great Britain, demand a special notice in this place.

The opening of an expanding and lucrative traffic with the far east of the globe, has called more imperatively for improvements in science and art, which the merchants of old, in their occasionally distant voyages, the less needed. To them indeed one item of daily expense was unknown;—the consumption of coal had not advanced the costs of a voyage to an enormous outlay, nor had the wear and tear of machinery entailed on shipowners disbursements which at this day form so prominent a feature in their aggregate yearly expenditure.

It was to meet this and to render facilities for shortening a voyage already diminished in duration by the use of steam, that attention was attracted to the long neglected practice of great circle sailing.

To explain the principles of this sailing it is only necessary to take an ordinary terrestrial globe, and notice that while some circles usually drawn thereon and called meridians are of equal size, because if the globe were cut in two in the plane of any one of these meridians, the section would pass through the globe's centre, other circles called parallels (as of latitude, declination, altitude, &c.) differ in magnitude. The term great circle only applies to the former: a sphere therefore being cut through on a great circle would be divided into two equal parts. The equator is of this description. If we take a thread and stretch along the equator, say reaching along 80 or 90 degrees of longitude, on tightening the thread it would still lie exactly along the line: such would also be the case on the meridians; but if this be attempted on any of the parallel circles, the thread on being tightened would slip off the parallel in a direction towards the nearest pole, thus forming an illustration of a great circle track; and the farther from the equator this is tried, the more striking would be the difference between the parallel and the track, which thus measures the *nearest distance between the ends of the thread*, and this will be the case wherever a thread is thus applied obliquely on a sphere.

A general belief prevails among merely practical men that this kind of sailing is one of recent development—that its employment has been in consequence of modern discovery; but such is far from the truth. Those who have studied the practice of navigation as given in old authors will be aware that for nearly 150 years before the dawn of this century a knowledge of great circle sailing was not only considered to be a necessary element in the acquirements of a navigator, but a knowledge of its very principles precisely as laid down in the most modern works (so far as regards construction and calculation) was thought an essential part of the educational course of every sea-going merchant captain, and its rules and demonstrations are to be found plainly set forth in such works as Atkinson's, Norwood's, Newhouse's, Gallibrand's, and others of the period of about 1680 to 1720.

Spherical trigonometry was naturally considered indispensable to every one employed in conducting treasure over the surface of a *sphere*, while a knowledge of plane trigonometry was deemed an equally necessary preparation for those whose voyages were so short as to admit of the sides of a triangle on the globe being for ordinary purposes considered as straight lines but the teaching of spherics to the navigator falling into disuse (by some extraordinary misconceptions), great circle sailing gradually became neglected, until for many years it was omitted in the standard works on navigation altogether. Even the attempt of Dr. Kelly, the mathematical examiner at the Trinity House nearly 50 years since, to renew the study of spheric projection, resulted in failure. Thus, while the sea officers of other nations are well prepared in that which forms not only the basis of great circle sailing, but of nautical astronomy, the energetic and intelligent mariners of England, although progressing in all else, were doomed for a time to wade in the pursuit of principles through works which as regards theory are somewhat too elaborate, and with respect to the rules of spheric construction are quite inadequate, for the mere navigator.

Such was pre-eminently the state of things when the late skilful and lamented Lieutenant Henry Raper, R.N., produced his 'Practice of Navigation,' which forms the present text book of the Royal Naval service, and of the higher classes of merchant navigators. But even in this admirable work the doctrine of spheric construction has been omitted as evidently forming no supposed essential in a sea officer's training.

The name of Raper must however be conspicuous as the regenerator of great circle sailing. In his work he gives excellent formulæ, but the use of logarithms *arising from rules not understood* by the uninitiated entails an effort of memory which is injuriously allowed to supplant the satisfaction which a conscious knowledge of principles would so unceasingly furnish. Notwithstanding this, Raper's solution of the "wearisome problem" of the great circle is eminently concise and practical, and for those who are content with spheric calculation, nothing more can be desired.

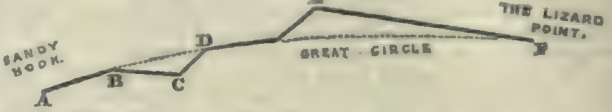
Soon after Raper's work appeared, Mr. J. T. Towson, examiner in navigation at Liverpool, devised a set of tables, by means of which, and an ingeniously contrived diagram called a "linear index," together with the aid of dividers and scales, he so greatly simplified the matter as naturally to affect the commerce of the country, inasmuch as voyages which formerly occupied nearly 150 days were principally by means of great circle sailing, and, together with improvements in ship-building [CLIPPER], performed in about 70 to 80 days. Hence the subject has become one of large pecuniary moment; and it must here in justice to Mr. Towson be stated, that he generously presented to the Admiralty for public use the tables which had been constructed by him through years of very great labour. He has subsequently been enabled to further facilitate the question by adding to his tables, in 1854, a column containing the means of ascertaining at once the distance between a ship and her destined port.

Various attempts have been lately made to supersede these tables: one of these deserves particular mention, not only from the elegance of the means employed, but from its leaving so little to be desired, although that little was important. It occurred to the Rev. Hugh Godfray, M.A., and to a merchant captain, Mr. Bergen, at about the same period, that a chart constructed on the gnomonic projection [GNOMONIC PROJECTION] would at once show the great circle track by laying any straight edge along the two given places: this certainly shows the track with great accuracy; but here again the aid of a second diagram, formed, too, by curves which convey at sight no elucidation of principles, was required in finding the "course and distance."

Popular errors exist on this question which are worthy of special notice. Navigators are accustomed to use charts constructed on Mercator's projection, wherein all bearings are taken as straight lines, and these straight lines cross all the meridians at the same angle, and therefore offer a convenient mode of sailing and a ready means of finding a course and distance; but from reasons already given, as explained in applying a thread to a globe, the same error in actual distance must exist on Mercator's charts, where the parallels are represented as straight lines, as are found on the surface of the globe itself; for a parallel of latitude in neither case exhibits the nearest track between two places lying on it: therefore, if we wish to show on a Mercator's chart the nearest distance between such two places, it can only be represented by a curve, and as a mathematical line is that which is the nearest distance between two points, those who forget that the straight lines on the Mercator's chart are, to answer a specific purpose, themselves actually distortions, are liable to doubt the soundness of the principle of great circle tracks.

And, again, a multitude of navigators at this day deny the possibility of sailing on a great circle curve, because, say they, such would require a continual change of course. As well may it be said that, because of the difficulties attending the quadrature of the circle, the use of the circle in ordinary mathematical computations is fallacious. This widely existing misapprehension would at once be demolished were this method of navigation called "tangent sailing;" such it really is; and the change of name was first proposed to the astronomer-royal in 1857 by Mr. Saxby; for it is the peculiar property of great circle sailing that, in contradistinction to Mercator's, no two meridians are crossed at the same angle. All that need be done, therefore, by a navigator is, to sail *as near to his great circle track as convenient*, and each *separate* course will be a *tangent to his track;* and the shorter those tangent courses can be made the more will the duration of a voyage be diminished. But where a method is used, the principles of which are little understood (for the terms lat. of vertex, long. of vertex, &c., suggest a difficulty to the untrained student), a ship standing too long on one course is liable to be found hundreds of miles northward or southward of her desired position; and this will be found generally to arise from the captain's using too frequently during the passage the same latitude of vertex with which he started, *and on which he calculated his courses for the voyage before leaving England.* The following figure will illustrate this. It is the memorable and unexaggerated track of a celebrated clipper across the Atlantic to England in the autumn of 1856, one of the then shortest passages on record.

Fig. 1.

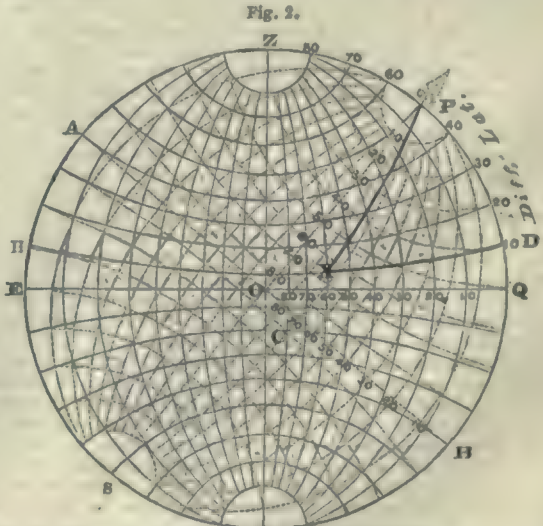


In the above it will be seen that on the ship's being found at C (at some distance from the dotted great circle A F between the two places), she was, to save calculation, hauled up for the great circle track, instead of being navigated on a newly-found track, and with, of course, a newly-found "latitude of vertex" in the tables used; while, on arriving at E, whither a heavy swell and S.E. wind had driven her, the captain abandoned his former track, and, prudently forming another, as at E F, completed his brilliant passage upon it with credit.

From this it appears that facilities were wanted whereby to further simplify the finding of a great circle course and distance; and as the astronomer-royal, the Trinity Board, and the Local Marine Board of London, and the highest authorities, approve of the use of the "spherograph" as the readiest and most intelligible means of navigating on a great circle, a case in illustration of its applicability is given below.

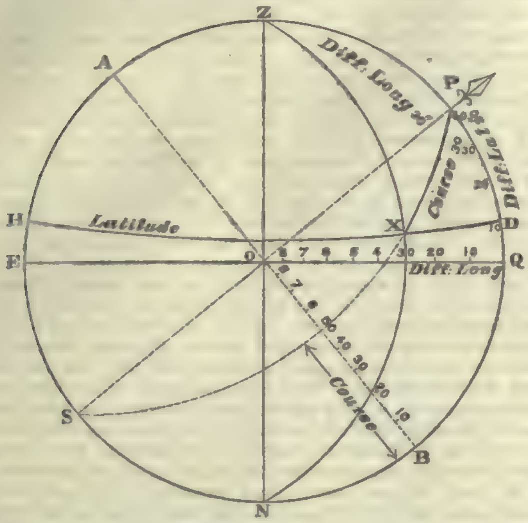
If we take two hemispheres on the stereographic projection, each having the usual meridians and parallels drawn thereon, and attach them so that they revolve concentrically, the *upper one* being made of some transparent material, we have the powerful patented instrument called the "spherograph." Its use in spheric navigation is as follows: suppose a ship to be in latitude 50° N., and bound to a port which is in lat. 10° N. and 60° difference of longitude westerly. The *figure* 2 will show the problem as *set* by the spherograph, in which the dotted lines are supposed to be *seen through* the upper sphere. The only manipulation required was the moving the under pole P to the ship's latitude, E Q being the equator. Then P D would evidently be the difference of latitude, and D X the difference of longitude, while P X would give at once the great circlet rack, and the angle X P D would show at once the course to be sailed; and counting the dotted parallels of the under sphere which cross P X, we evidently read off the number of degrees in the distance between P and X, which multiplied by 60 gives the nearest distance in geographical miles. Hence the course X P D (measured at 90° from the angular point P), or at C B, would be about 72½° (or S. 72½° W., because the diff. of lat. and diff. of long. are southerly and westerly by question), and the distance X P = about 63½° × 60 = 3810 miles.

Fig. 2.



Suppose, in addition, the ship, when next able to ascertain her position was found to be in latitude 40° (instead of 50°), and having only 30° of longitude to make. We should now, as in *fig.* 3, set the under pole to 40° north latitude and (omitting all unnecessary lines for the sake of clearness) the line D X would represent the difference of longitude, 30° and P X the distance, while the spheric angle X P D would be the

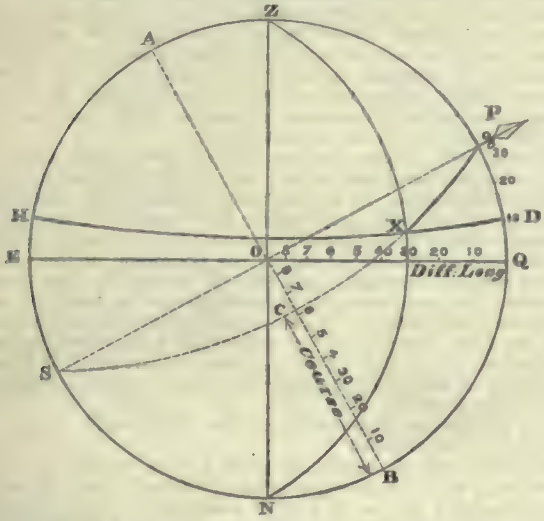
Fig. 3.



required course; and being measured on C B, would give 50°, or (S. 50° W.), and the distance P X would be found as in *fig.* 2.

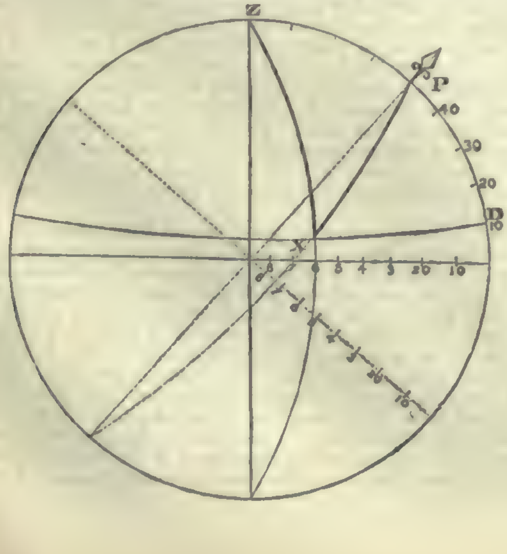
Suppose, further, the next ascertained position of the ship to be in lat. 30° N., and the diff. of long. 30° (as before). The under pole P being

Fig 4.



moved to 30° N., would show the problem as in *fig.* 4, which would be solved as in the above, giving the course about 60° or S. 60° W.

Fig. 5.



The mathematician will have noticed that the useful problem of great circle sailing is solved in the spherograph by means of a triangle, differing from that generally used in its solution by calculation, an example of which it is essential to give. For while by the latter we use the two zenith distances with the difference of longitude, in the instrument we simply take the latitude in, and the latitude bound to, and the difference of longitude. Instead of using triangle X Z P as in calculation, we use the rational triangle X P D.

Fig. 5 represents the problem given in *fig.* 2, as adapted to the following computation :—

Let Z P be the co. lat. 40°, and Z X be the co. lat. 80°, and the angle P Z X be the diff. of longitude 60°. To find the distance P X, and X P Z, the complement of the first great circle course.

Z P = 40° . . 40° Angle P Z X = 60°
Z X = 80 . . 80
30 ½ contained angle.
120 sum . 40 diff.
60 ½ sum . 20 ½ diff.

As sine ½ sum 2 sides	60°	ar. co.	0·062469
To sine ½ diff. . .	20	„	9·534052
Cot. ½ contained angle	30	„	10·238561

9·835082 = tang. ½ diff. of the other two angles, or 34° 22′.

As cos ½ sum 2 sides .	60°	ar. co.	0·301030
To cos ½ diff. . .	20	„	9·972986
Cot. ½ contained angle	30	„	10·238561

10·512577 = tang. ½ sum of the other two angles, or 72° 55′

½ sum 72° 55′
½ diff. 34 22
Sum 107 17 = co. course X P Z, and 180°—107° 17′ = the course Q P X, or 72° 43′.
Diff. 38 33

∴ To find the distance P X—

As sine X P Z .	107° 17′	ar. co.	0·020065
To sine Z X .	80	„	9·993551
So sine P Z X .	60	„	9·937531

9·951147 = sine 63° 20′
60
3800 the distance in geographical miles.

The instrument, however, has this advantage over all other methods, namely, it takes the simple data alone as they occur in practice, without there being necessity for the terms hitherto found convenient, such as lat. of vertex, long. from vertex, &c., or indeed even the co. latitudes, co. courses, &c., and the tyro is thus only using terms in the spherograph which *he thoroughly comprehends.*

We have now shown that it is really easier to navigate on the great circle than by any other method. The applying of parallels to a common chart in order to obtain what is actually an *erroneous* course, occupies more time than using the spherograph to find the course which leads *directly* to the place bound to.

If anything could be more simple, it is to be found in the tables which accompany the instrument, and which are derived from spheric calculation, and have no connection with the diagrams, except that they verify the accuracy of instrumental projection. We give an example as worked in these tables. Taking the question in the above *fig.* 4, namely, lat. of the ship, or "*Lat. in*" 30°, diff. of long. 30°, diff. of lat. 20°, we will suppose a block of figures (omitting such as are unnecessary for our illustration) to be as under ;—

Ship's lat. in	Diff. of lat.	Diff. of longitude. 5°	10°	15°	20°	25°	30°	35°	40°	45°	50°	55°	60°, &c.
30°	5°	..	..	..	..	..	..	..	..	..	..	..	..
	10	..	..	..	..	..	..	..	..	..	..	..	..
	15	..	..	..	..	..	..	..	..	..	..	..	..
	20	..	..	..	..	..	60	..	..	..	..	..	..
	25	..	..	..	..	..	..	..	..	..	..	..	..
	30	..	..	..	..	..	..	..	..	..	..	..	..
	&c.												

The intersection of the vertical and horizontal lines at "60," having reference to the data, shews the great circle course to be S. 60° W., as measured at B C (*fig.* 4).

The not easy consideration of composite sailing [SAILINGS], is henceforth entirely superseded by the following general rule in determining the course of a voyage, and its importance to maritime commerce cannot be over-rated. A navigator with the chart before him, and possessing a spherograph, will in future reason thus with himself: "Being anxious to make the shortest possible voyage, I must not let great circle sailing take me into difficulties as to dangers, baffling winds, ice, &c.; no, I shall for very many reasons like to place my ship *there* and *there*, on my route" (at the same time marking dots on his chart to indicate such places). We need only imagine P in *fig.* 2, to be one of those dots, and X another,—always supposing one of the places to lie on the primitive circle, which in all cases represents the ship's meridian—and the extreme simplicity of this new method by spherograph, to the total exclusion of what has been called "composite" sailing, will be at once apparent.

Hitherto whatever obstacles may have prevented the general renewal of the practice of great circle, or tangent, navigation, a knowledge of such obstructions has been confined almost to navigators alone; but henceforward (and our so thorough investigation of this important subject as a national question bearing with weight upon extensive interests, has been with this object) it will remain with shipowners and underwriters to see that their treasure is conveyed from place to place in the *shortest possible time;* for to take a melancholy example, it must not be forgotten that had the unfortunate "Royal Charter" been able, by any extra facilities possessed by her late accomplished Captain, to reach Point Lynas even *twelve hours earlier*, the awful catastrophe which desolated so many homes, and wrung so many hearts, would most probably have been averted.

GREAVES. [ARMOUR.]

GRECIAN ARCHITECTURE. The most ancient constructional remains in Greece are the rude pre-historic masses of masonry known as Cyclopæan, from their being attributed by early tradition to the fabulous Cyclopes. They consist chiefly of walls formed of huge shapeless blocks of stone, having the interstices filled up with smaller but equally rude blocks. Of a less uncertain but still remote period are the Pelasgic remains, which, though remarkable rather as constructive works than as works of art, are yet for many reasons not devoid of interest in the history of architecture. They belong however to a non-Hellenic people, and have little affinity with the true Grecian architecture; and therefore will be noticed under a separate head. [PELASGIC ARCHITECTURE.]

Without here entering upon an examination of the history of Grecian architecture, we may briefly observe that it is now generally admitted that, although in its ultimate development it is beyond dispute the creation of the Hellenic mind, the germs of it were derived from the architecture of older nations: its grander elements and more solid proportions from Egypt; its lighter characteristics and more ornate features from Asia. The great distinction of Grecian architecture lies in its orders: these are the Doric, Ionic, and Corinthian. Of these the Doric is the oldest, and it is noteworthy not only that in the oldest known example, a temple at Corinth of the 7th century, B.C., are the proportions far more massive and the whole more pervaded by Egyptian feeling than in later temples, but that there still exists a tomb at Beni Hassan in Nubia, supposed to be of the age of Rameses II., at the entrance of which are two fluted columns clearly the prototypes of the Grecian Doric; while, as Sir G. Wilkinson has shown ('Ancient Egyptians,' vol. ii. p. 125, and Plate vii.), the characteristic Doric *fret* border was also a common Egyptian ornament. The more graceful Ionic order, on the other hand, may clearly be traced to Asia. As Mr. Fergusson has pointed out, there occur in the ruins of Persepolis several columns which have the Ionic volutes, but placed vertically instead of horizontally. On slabs found in Khorsabad by M. Botta, however, and in others brought from the same locality, and now in the British Museum, are sculptured representations of buildings with columns crowned with volutes precisely as in the Greek Ionic. The Ionic guilloche ornament is also found both at Persepolis and Khorsabad. The latest of the three Greek orders, the Corinthian, is equally a derived one with the others. As was shown in the article COLUMN, the bell of the Corinthian capital of the temple of Apollo at Bassæ, near Phigaleia, closely resembles the Egyptian capitals placed alongside it; and in one of the two remaining Corinthian buildings in Greece, the Tower of the Winds, at Athens, there are no volutes to the capitals, and the leaves of water-lilies adhere, as in Egyptian examples, close to the bell.

But if the architecture of the Greeks, like that of every other people, was derived rather than invented, all that gave to it its life and power is its own. The exquisite feeling for beauty of proportion, majestic simplicity of form, truth and purity of expression, and perfect adaptation to its purpose, all those higher constructive and æsthetic qualities, in short, which place it so far above the architecture of all other countries, only Greece can lay claim to.

The religious edifices of a people are nearly always the surest indication of the state of their architectural tastes and ability. Fortunately perhaps the temples are almost the only buildings of ancient Greece which have come down to the present day in a sufficiently uninjured condition to permit of our forming a fair estimate of them. The oldest left is believed to have been built about the middle of the 7th century, B. C.; one or two others are of the 6th century, but the finer examples belong to the 5th and 4th centuries, B. C. The classes, forms, and architectural character of the temples will be described under that title. [TEMPLE.] The public buildings devoted to secular purposes of which any remains exist consist chiefly of theatres, agora, thermæ, &c., and these too are noticed elsewhere. [THEATRE; FORUM; BATH, &c.] Of the palatial residences and private houses, only imperfect written descriptions are left. One or two small monuments however, as the Choragic Monument of Lysicrates, and the Tower of the Winds—both comparatively late works and both Corinthian in style—remain as proofs of the exquisite taste and skill which the Greeks could exert on their less important secular structures.

Greek architecture differs from all subsequent styles in being non-arcuated. Whether the Greeks were acquainted with the arch or not, they did not employ it in their public buildings. The great constructive feature is the beam. Greek architecture consequently is essentially *horizontal* in principle: its primary lines are horizontal, its secondary vertical. Hence stability, solidity, are its constant characteristics. Yet though rectilinear in appearance it is not strictly so in fact. So sensitive was the Greek eye to the slightest deviation from perfect beauty of expression, that the architects resorted to a singularly refined contrivance to overcome an optical illusion so small that no other people probably would ever have noticed it. Right lines when protracted far above or on either side of the spectator no longer seem perfectly straight, but are slightly bent in accordance with the laws of perspective. Contrasting right lines, and even contrasts of light and shade in like manner cause an appearance of deflection. To remedy these and other corresponding effects, it has been recently found that not only did the Greeks, as has long been known, give their columns a slight *entasis*, or swell near the middle, but they made the boundary line a delicate parabolic curve; and instead of placing the axes of the columns as was always supposed quite vertical, they inclined them in a small measure inwards. They also gave to the pavements on which the columns rested, and the steps of their temples, a minutely convex character, the rise in the centre being about three inches in a hundred feet. Further, the horizontal lines of the entablature were curved in a precisely correspondent manner, and other minor adjustments made. But all these minute curves were executed with such exquisite knowledge and skill, that the effect was simply that of rendering the spectator unconscious of any deviation from a mathematical right line; and it is only by the most careful observation that the contrivance is even now detected. The discovery of these curves was made by Mr. J. Pennethorne, in 1837, and soon afterwards (we believe independently) by Messrs. Hofer and Schaubert; but their existence was placed beyond doubt, and the principles upon which they were carried out clearly evolved by Mr. Penrose, who spent a considerable time in Greece investigating the subject and making careful and repeated admeasurements: the results of his researches were embodied in his 'Principles of Athenian Architecture,' published by the Dilettanti Society in 1851. These refined optical corrections seem to have been always most perfectly developed in temples of the Doric order, but they are found more or less in most others.

It is in Doric temples too that another great artistic feature was most effectively developed, namely that of the introduction of sculptural ornamentation. In all Greek temples sculptured ornament was freely introduced, but in the nobler Doric temples it appears in its greatest perfection. In the cella were introduced friezes in low relief; in the metopes alti-relievi, and in the tympanum of the pediment statues entirely detached. And that these were, at least in some instances, the masterworks of the sculptor's art we have evidence in those marvellous reliques which once adorned the Parthenon, and are now the glory of the British Museum [ELGIN MARBLES], while that their adjustment to their respective places was the result of a perfect knowledge of sculpturesque effect may be seen by a reference to the article ALTO-RELIEVO.

The polychromatic decoration of the temples will be spoken of elsewhere. [POLYCHROMY.]

The three Greek orders characterise three periods in Grecian architecture much as the three styles of Pointed Gothic characterise three important phases in English architecture. Doric, the oldest, corresponding in seniority and character to our First Pointed, the true English Doric, is marked by a sober grandeur and simple dignity, yet withal is preeminently beautiful. The Ionic, which follows in order of time, more graceful, easy, and flowing in style, corresponds not inaptly to our Second Pointed or Decorated. While the luxuriant Corinthian, the product of the later years of Greek art, and the herald of its decline, finds its parallel in our florid Third Pointed or Perpendicular. [GOTHIC ARCHITECTURE.] But in one respect there was a broad difference. The Gothic of either class was the exclusive style of its epoch. The Decorated did not tolerate the Early English, nor the Perpendicular the Decorated. The Greek orders, though they were the product of different ages continued to flourish contentedly together. Ionic did not suppress Doric nor Corinthian Ionic, but the elder and the younger simultaneously filled the places for which each seemed most fitted.

Before noticing somewhat more in detail the orders of Grecian architecture, it is necessary to explain that what is termed an Order consists of two principal divisions, the *Column* and the *Entablature*—*i. e.*, the upright support and the horizontal mass supported by it. The Column is again divided into *Base*, *Shaft*, and *Capital* (except in the Doric order, where the shaft rests immediately upon the flooring.) The Entablature is also divided into three parts—the *Architrave*, or Epistylium, *Frieze*, and *Cornice*. These together constitute the Order; which is further distinguished as belonging either to the Doric, the Ionic, or the Corinthian style, according to certain general proportions and characteristic embellishments. The scale for the proportions—that is, not the actual but the relative dimensions of the different parts compared with each other—is taken from the lower diameter of the shaft of the column, which is divided into two modules or sixty minutes. Modern systematisers, who have laid great stress upon proportions, have, contrary to the practice of the Greeks themselves, attempted to fix certain invariable proportions for each order; and some have maintained that by them, quite as much as by peculiarities of detail and embellishment, the character of an order is determined. In regard to proportions, however, even greater discrepancy is found between different examples of the same order, than between two distinct orders. We must therefore attend to certain indicial features and marks by which the particular order may be immediately recognised; thus the absence of base or mouldings at the bottom of the column, the plain capital composed of merely an echinus and abacus, and a triglyphed frieze, enable us to pronounce at once that the order is the Doric. In like manner the voluted capital, or the foliaged one, as distinctly denotes that it is either Ionic or Corinthian. In regard to the two last-mentioned, the principal distinction between them is confined to the capital; there being no other determinate difference between the columns or the entablatures of the one or the other. Were we to see only the shaft of the column, we should be able to decide from that alone whether it were Doric or not; the flutings peculiar to that order being broad and shallow, and forming sharp ridges or arrises on the circumference of the shafts; whereas in the other two they are narrower and deeper, rounded at their extremities, and divided from each other by fillets or spaces left between the channels on the surface of the shaft. In like manner were we to see the fragment of an architrave, we could pronounce with tolerable certainty whether it was Doric or not; although in the latter case not quite so clearly whether it was Ionic or Corinthian. The Doric architrave consists of a single plain face surmounted by a broad fillet, here termed the tænia, to which another fillet with small cylindrical guttæ or drops is attached beneath each triglyph; but the architraves of the other two orders are divided into (generally) three faces or faciæ, slightly projecting one above the other, and crowned by curved mouldings, sometimes plain, but more frequently enriched. By attending to these few simple and obvious distinctions, no one can feel any difficulty in ascertaining the particular order to which a building belongs. Illustrations are given of the details of the entablatures of the several orders under COLUMN.

Peristyle of the Parthenon.

Doric Order.—In attentively examining the Grecian Doric, we can hardly fail to note what admirable taste and study of effect it exhibits throughout, and how every part is made to conduce to the character of the whole. The columns are of short proportions, the entablature deep; the former have no bases, which, owing to the narrowness of the inter-columns, would have proved highly inconvenient, and instead of producing an air of finish would rather have occasioned heaviness. The proportions themselves are such as to reject any addition of that kind at the lower extremity of the column, because the difference between the upper and lower diameter—which, owing to the shortness of the shaft, occasions so visible an inclination as to produce the effect of tapering upwards—causes it also to appear to spread out below in such manner that the lower extremity becomes a sufficiently wide basis. This inclination is further rendered more apparent than it would be by the outline alone of the column, owing to the lines being repeated in the fluting. The fluting, while it diminishes the heaviness, produces great variety of light and shade in every direction; and the mode of fluting peculiar to this order is admirably in unison with the expression of all the rest, the channels being wide and shallow, and separated from each other by mere ridges on the surface; both which circumstances contribute to that breadth and simplicity which pervade the other parts. No less appropriate and well imagined is the capital, which consists of little more than an echinus and deep square abacus above it; the former expanding itself out from the neck, or upper part of the column, until its diameter becomes equal to that of the foot of the column: in reality, it is something greater, but not more so than is requisite to counteract the apparent diminution caused by the greater distance from the eye. Thus harmony is kept up between both extremities of the column, verticality is restored, the projection above (as in the case of the sloping wall and coved cornice of Egyptian structures) is made to restore perpendicularity by adding just as much as had been taken away by the diminution of the shaft upwards, and a play, variety, and contrast are produced, unattainable by any other mode.

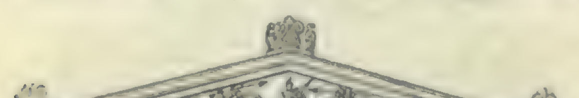
The architrave is plain and deep, well proportioned both as to the weight which it has to bear and to the column below, its average height being equal to the upper diameter or narrowest part of the column. The width of its *soffit*, or under side, is about a medium between the two extreme diameters, so that it overhangs the upper part of the shaft; yet it is not so broad as the abacus of the capital, which by opposing a greater surface to it appears better calculated to support its pressure. The frieze is generally of the same dimensions as the architrave, very rarely deeper, in some examples not so deep. The *triglyphs* which decorate it, and are peculiar to the order itself, are upright, slightly projecting tablets (in width rather more than half the lower diameter), channelled with two grooves or glyphs (γλυφαί), and with a half groove chamfering off each of its outer edges. The spaces between these ornaments, which were originally intended to represent the extremities of the beams (whether stone or timber) resting upon the architrave and forming the inner roof or ceiling are

The Parthenon.

square, or nearly so, and are distinguished by the name of *metopes* (μετόπαι; *i. e.* openings or intervals. They are in fact so many small panels, and were generally filled with sculpture in bas-relief, although there is hardly an instance of the kind in any of the numerous modern imitations of the Greek Doric. Beneath each triglyph is a series of small *guttæ*, or cylindrical drops, attached to a fillet, just under the moulding of the architrave, to which division of the entablature they may be said to belong, although evidently a continuation of the ornaments on the frieze. Some suppose them to have been intended to represent nails, others drops of water running down the channels of the triglyphs and settling beneath them; be that as it may, they certainly contribute in no small degree to architectonic expression and effect, inasmuch as they break the monotony of line, and by extending some ornament to the architrave bring it into harmony with the frieze. The space between one triglyph and another being regulated by the height of the frieze, since each interval or metope forms a square, this circumstance also regulates the *intercolumniation*, or distances at which the columns are placed; because as there must be a triglyph over every column, there cannot be more than one triglyph over each intercolumn, unless the latter be increased to the extent of another triglyph and metope; that is, made half as wide again. Consequently there are hardly any instances of more than *monotriglyphic* intercolumniation (that is, with more than a single triglyph over each intercolumn) in Grecian buildings, except when the centre intercolumn is made wider than the others, as in the Propylæa at Athens, where a ditriglyphic arrangement is employed.

Like every other part of the order, the Doric cornice is composed of few and bold parts; it consists of little more than a corona (the projecting and principal member in every cornice), finished above by one or two simple mouldings, and having attached to its soffit a series of shallow plates or tablets, studded with guttæ. These are termed *mutules*, and are the peculiar distinctive marks of the Doric cornice, in like manner as dentils are of the Ionic, and modillions of the Corinthian. They may be considered as being to the cornice what the triglyphs are to the frieze, and there is one corresponding to each metope as well as each triglyph; which produces a beautiful gradation of parts, for as there is an additional triglyph between every column, so is there an additional mutule between every triglyph; whereas, were there no more triglyphs than columns, and no more mutules than triglyphs, the effect would be both monotonous and poor, and these different features would be confined to distinct lines from top to bottom. The average height of the entablature is about two diameters, or one-fourth of the whole order, taking the height of the column at six diameters.

The sloping or *raking cornices* of the pediment resemble the horizontal one, except that there the mutules are omitted. In order, however, to give increased depth and importance to the pediment, as the finish of the whole structure, its cornices have an additional member, termed by some the *epitithedas*, consisting of an ovolo, or convex moulding, or a cymatium; sometimes deeper, sometimes shallower. This *epitithedas* was continued a little way at the angles, where it usually terminated against a block, carved with a lion's head, or some other ornament. The face of the pediment itself, termed the *tympanum* (called by the Greeks ἀετός, ἀέτωμα), was almost always filled with sculpture. The pediment was invariably of a low pitch, but not always of the same pitch; on the contrary, whatever the span might be, its height continued nearly the same, it being more or less acute, in proportion as the portico was narrow or broad: its average height was equal to that of the entablature, and either a little diminished or increased according to circumstances, but hardly ever so much as to render the tympanum deeper than the entablature. The accompanying cut showing the portico of the Doric temple of Athene at Ægina as restored, will illustrate many of the leading characteristics of the Doric style as here pointed out.



Front Elevation of the Temple of Ægina, as restored.

A list of the principal Doric temples is given under COLUMN; as convenient practical examples of this order, where the reader may study its character, and learn to distinguish, in actual buildings, the various members and particulars here pointed out, not, be it remembered, as faithful illustrations of the æsthetic principles of Grecian Doric—we refer to the portico entrance to the North-Western Railway Terminus, Euston Square, and the Corn Market, Mark Lane, in which latter the frieze is decorated with wreaths instead of triglyphs—as in the monument of Thrasyllus at Athens—and consequently the spaces between them cannot be called metopes.

In the *Ionic Order* the column differs widely from that of the Doric, not only in the form of its capital, and in having a base, but in the contour of its shaft and the mode of fluting, it being more slender and not tapering so suddenly. The base is generally that termed the Attic-base, composed of two tori, or convex rings, with a concave moulding, the scotia, between them; for as the Doric character demands plane surfaces and lines, so does the Ionic require curved mouldings and contours, as harmonising with the curved forms of the volutes of the capitals. To prevent the harshness which would result, if the mouldings forming the base jutted out abruptly from the lower end of the shaft, the latter is made to spread itself out immediately above the base in a sweeping curve, termed the apophyge. The number of the flutings of the shaft is increased from twenty to twenty-four; besides which there are spaces left between them (fillets); for the mere arrises or sharp edges, peculiar to the Doric or earliest mode of fluting, would be utterly at variance with the rounded contours of the base and capital. The channels themselves being thus multiplied and set apart from each other, are consequently much narrower than those of the other order, and considerably deeper in proportion to their breadth; and instead of terminating in flattish curves, their extremities are made the half of a circle, or an ellipse: all which circumstances contribute to uniform delicacy of expression. It should be observed, too, that the upper torus of the base was generally fluted horizontally, thereby producing uniformity of decoration between that and the shaft, with contrast as to the mode of applying it. When not so fluted, that torus was sometimes enriched with a *guilloche*, a beautiful sort of chain-like ornament sculptured on its surface: see example in the cut of the base of an Ionic column from the Erechtheium under COLUMN.

The capital may be described generally as consisting of two faces, about as wide, measured across the volutes, as the base—that is, a diameter and a half, or 90 minutes; which breadth is divided into three equal parts (more or less), 30 minutes being allowed for each volute. These volutes are composed of spiral mouldings, which make several revolutions, and gradually become narrower as they approach what is termed the eye or cathetus; in the richer capitals of this class there are intermediate spirals, following the course of the other; the spaces or interspirals, forming slightly concave surfaces (see diagram under COLUMN). In all the Athenian examples there is also a flowing or festoon hem forming the lower edge of the face between the volutes, whose curve harmonises most beautifully with the outline of the volutes themselves; whereas, in the capital of the Asiatic Ionic, as well as the Roman and modern Italian, the volutes are here connected by a straight line. Immediately beneath this part of the capital is a carved convex moulding, to which succeeds the echinus or ovolo (so called because cut into the form of eggs), and lesser mouldings. The idea of an Ionic capital therefore seems to have been that of introducing an ornamental mass between the echinus and abacus of the earlier shaped capital, and rolling up its deep projecting extremities into volutes. Besides the capital (properly so speaking, where additional richness was required, and also increased height for the column, without much increasing that of the shaft), a necking, enriched with sculpture, and separated from the shaft by a carved convex moulding, was introduced. The abacus is square in plan, and its sides form a cyma reversa, or ogee moulding, either carved or plain, according as the capital itself is more or less enriched. But the capital itself, at least that portion of it occupied by the volutes, is not so deep on its sides as on the two faces; the reason for which is obvious, because either those faces must have been much narrower, or if this part formed a perfectly square mass of a diameter and a half, it would overhang the upper parts of the shaft, and project beyond the architrave in a most unsightly manner. The baluster sides of the volutes, as they are termed, are, for the sake of elegance and lightness, hollowed out so as to assume something of the appearance of two tubes or horns, whose broader extremities or mouths come against the back of the volutes. The capitals at the angles of a portico are frequently differently arranged, since, in order to obtain a face on the return similar to that in front, the outer volute is turned diagonally, so as to serve for both faces; a mode adopted for all the capitals, without distinction, by many Italian architects. The architrave is divided into three nearly equal faciæ, projecting very slightly one over the other, and crowned by a cyma recta moulding, carved or plain, as the rest happens to be more or less enriched. The caryatid figures, which in some buildings of this order supply the place of columns, are noticed under CARYATIDES.

The cornice in Athenian examples is exceedingly simple, consisting only of two mouldings beneath the corona, the uppermost being within the hollowed soffit of that member; nor do dentils, which are generally reckoned the distinguishing marks of the Ionic cornice, appear to have been used, except by the Asiatic Greeks. Consequently, unless the frieze be enriched with sculpture, so as along with the cornice to produce a rich ornamental mass above the architrave, not only is the cornice apt to appear meagre, but the whole entablature to look cold and naked, even plainer than that of the Doric order, and to offer anything but a pleasing contrast to the elegant richness of the capitals below it.

What has already been said in regard to the pediment will suffice for this order likewise, there being no other difference than what is occasioned by the cornices themselves. But having thus far explained the two chief Greek orders or styles of columns, in regard to columns and entablatures, we now proceed to notice what in certain situations are employed as adequate to, or substitutes for, columns, namely, *antæ*, or pilasters. In Italian architecture, pilasters are very frequently employed in lieu of columns, or are placed against a wall to correspond with a range of columns in front of it; their bases and capitals, too, are made to correspond with those of the columns, as far as the difference between a square and circular plan will allow. The Greeks, on the contrary, never employed antæ, except at an angle or the extremity of a wall; and instead of aiming at perfect similarity, they purposely gave to such pilasters, bases and antæ-caps, dissimilar from those of the columns; neither did they diminish them, but made them of the same width above and below, which width was determined by that of the soffit of the architrave, and was therefore something less than the lower diameter of the column, but greater than the upper one, since both in the Doric and Ionic the architrave overhangs the upper part of the column. Thus they kept the antæ and columns quite distinct in character, thereby producing variety and contrast without injury to consistency. Sometimes the Doric anta has a simple kind of moulding and groove at its foot, which seems requisite to detach it from the wall, whereas the plain foot of the column resting on the pavement or steps defines itself to the eye quite sufficiently. The Doric anta-cap is very simple, and its abacus and other mouldings much narrower than those of the column-capital.

Although more ornate than those of the Doric, Ionic antæ-caps differ still more than the others do from the capitals of their respective columns, inasmuch as they have nothing whatever answering to those exceedingly characteristic features, the volutes; nevertheless they are so strongly marked by the same style as to render it impossible to mistake them, or attribute them to any other order. Between the bases of the antæ and those of the columns there are very slight differences; the chief is that besides the upper torus being fluted like that to the base of the column, the under one is also enriched, but by reeding or convex mouldings. There is also an additional concave sweep moulding placed beneath the torus. It is further to be observed, that antæ are never fluted, as is generally the case with Roman and Italian pilasters whenever the columns are so, and consequently a stronger distinction is kept up between the antæ and the columns.

In the above sketch of this order we have merely pointed out in a general manner the leading characteristics, without taking notice of the very numerous varieties, since hardly any two examples are perfectly alike, and some are strikingly dissimilar from any other. One of the most remarkable is that of the internal order of the Temple of Apollo at Bassæ, near Phigaleia, in Arcadia. The base, which is altogether different from the Attic one, is of great diameter compared with the shaft, which spreads down to it with a sudden sweep; hardly less peculiar is the style of the fluting, the channels being very broad and shallow, and the fillets very narrow, while the extremities of the channel are hardly curved at all, so that it seems but the first remove from Doric fluting. The capital is still more extraordinary, inasmuch as there are four voluted faces; at least there would be, if the columns were not attached to projecting piers. In order to effect this the faces are made concave, so that the volutes turn out towards the angles, and are placed at only half the usual distance from each other, so as to reduce still more the width of each face, else, as has already been remarked, the capital being square, it would be too bulky for the column. In its detail this capital is so plain that it looks very much like one of the earliest essays at a voluted capital; nor is it improbable that at first the design was to make such capitals perfectly square like the Doric abacus, and to produce four uniform voluted faces.

Under COLUMN will be found a list of the principal Grecian Ionic temples. One of the best modern specimens of Athenian Ionic is the portico of St. Pancras' church, London, by Mr. Inwood, a well-finished copy of one of the most florid specimens of the order, that of the Erechtheium. On the lateral porches at the eastern end he has given an application of caryatides supporting an entablature after the small building called the Pandrosium, attached to one angle of the Erechtheium. Other modern examples of the Ionic order in the metropolis are, the British Museum, the Post Office, the India House, which is more Asiatic Ionic than Athenian; and the portico of the College of Surgeons, Lincoln's-inn-fields.

Corinthian Order.—Though the small structure at Athens, called the Choragic Monument of Lysicrates, furnishes one of the most exquisitely designed examples of the Corinthian or foliaged-capital order that have been preserved to us, it is almost a solitary extant instance of the application of it by the Greeks; since the capitals of the small columns of the Tower of the Winds, have merely a single row of acanthus leaves at bottom. It is true that some magnificent edifices belonging to this order, such as the Temple of Jupiter Olympius at Athens, were erected in Greece; but they belong to a later period, after the order had been extensively employed by the Romans, who must be regarded as having brought it to perfection as a distinct style. That the order was derived in the first instance from Egypt we have already seen; eventually the Greeks added the Ionic volute, and produced a composite order entirely their own. In the Tower of the Winds, at Athens, the height of the column is little more than eight, in the Monument of Lysicrates it is nearly ten, diameters. [COLUMN.] In the former example, as we have seen, there are no volutes, and the upper row of leaves are those of the water lily. But the Lysicrates and later capitals are composed of two rows of acanthus leaves [ACANTHUS], those of the upper row springing up from between the lower ones; and from the sides of the centre-leaf spring out other leaves, whence emerge the helices or spirals, placed diagonally to support the extremities of the abacus, besides lesser spirals which meet, and sometimes intertwine each other above each middle leaf. The abacus itself, which is peculiar to this order, may be described as square in its general plan, but having its sides made somewhat concave, so as to curve out towards the angles, yet not overhang the body of the capital. The Corinthian entablature differs little from that of the Ionic, except in the cornice being made richer and deeper, and the number of its members being increased, in order to harmonise with the deeper capital of the columns. One of the features peculiar to it is the series of modillions or small brackets supporting the corona. We have mentioned the two Athenian examples of this order. In the metropolis most Corinthian capitals are Roman. But an imitation of the Temple of Lysicrates occurs oddly placed on the church of St. Philip, Regent Street, to serve as a belfry; and a careful restoration of it may be seen in the Crystal Palace, at Sydenham.

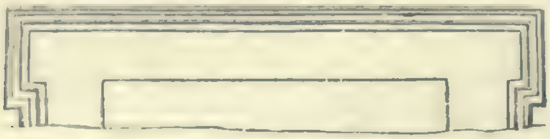
For all that concerns the plans of Grecian temples, their peculiarities of construction, and the terms employed to express their varieties, as designated from the number and position of the columns, we must refer the reader to the articles TEMPLE, and PORTICO; but it will be more convenient here to explain some points in the arrangement of columns, and other matters which are distinctive of Greek architecture.

In regard to *Intercolumniation*, or the distances at which columns are placed from each other, and upon which so much of their effect depends, it has already been mentioned that in the Doric order this is regulated by the triglyphs, and that monotriglyphic intercolumniation may be considered as the extreme of pycnostyle (thickly set), as it will sometimes occasion the columns to be less than a diameter and a half apart, the limits assigned to pycnostyle. But this of course depends upon the proportion which the metopes and triglyphs bear to the lower diameter of the columns. That such very close arrangement should be employed for the most solid of the orders, would almost appear an incongruity; yet it should be observed that in reality this arrangement is not so close as it appears to be when expressed by the proportion which the foot of the column bears to the intercolumn, because the shafts taper so much that what would be an inter-column of less than a diameter and a half below, would be two of the upper diameters, or more, above. The second mode is termed *systyle*, or two diameters apart; the third *eustyle*, or two and a quarter; the fourth *diastyle*, or three diameters; and, lastly, *aræostyle*, or four or more diameters. But the precise spaces thus defined do not seem to have been adhered to; and the Greeks, who appear never to have worked according to fixed rules, although precise rules have been since laid down from their works, seem to have allowed themselves any intermediate interval from a diameter and a quarter to two diameters, which they rarely exceeded, except when particular circumstances required it, and when the columns themselves were so small, that had they not been more than two diameters apart, the intercolumns would have been inconveniently narrow. When the columns are pycnostyle or less than two diameters apart, they produce richness not only by their increased number in a given space, but also owing to their being forcibly relieved by the increased depth of shadow behind them.

So far from employing pedestals to columns, which some have considered as forming as essential a part of an order as the entablature, the Greeks placed their columns immediately on the floor, or uppermost step; the whole temple being generally raised on a low platform, to which the ascent was usually by three deep steps, or gradini, serving as a base to the edifice. The depth of the steps was not accommodated to the human stature, but regulated so as to accord with the dimensions of the column: it has, therefore, been conjectured, that either a sloping platform of wood, or lesser steps of the same material, were employed as the real ascent to the temple. The Greeks invariably placed their columns singly, never in pairs, as has frequently been done by modern architects, and which, if not indefensible, ought never to be resorted to, unless required by positive necessity. Of engaged columns,—that is, columns half or three-quarters of a circle in plan, and placed against a wall as if built into it,—there are so very few instances in Grecian architecture, that they are to be considered merely as exceptions. One such authority for the use of half-columns occurs in the west front of the triple temple, or Erechtheium, at Athens [see plan under ERECHTHEIUM]. In the Italian or Palladian school, they prevail almost to the exclusion of insulated columns. Yet not only is much of the effect of the columns themselves lost, but also that of light and shade. But if something like the authority of the Greeks themselves can be pleaded in support of engaged columns, it cannot be adduced as countenancing a barbarism to which that practice and the employment of wide intercolumns gave rise, namely, that of making a break in the entablature above every column, and thereby destroying the continuous horizontal line of that part of the order, and carrying the vertical ones up into it. Another practice, not observed in any extant Greek building,[*] is that of supercolumniation, or the placing one order upon another, sometimes even to the extent of three or more; the diameter of the columns decreasing, and of course the width of the intercolumns increasing as they ascend. Inigo Jones's building called the Banqueting House, at Whitehall, affords an example of supercolumniation, together with one of engaged columns and broken entablatures.

Although the name itself would seem to show the contrary, Grecian architecture affords no precedent for what is termed an Attic order,—that is, a series of dwarf pilasters crowned by a cornice; and balustrades, also, are of modern invention. [Attic.] The only thing of the kind in ancient examples, and that of exceedingly rare occurrence, is a low and plain unbroken podium, or parapet; that is, without pilasters or other projections, above the cornice of a building. Far from attempting to conceal the roofs of their temples, the Greeks not only made them very conspicuous in the outline of the pediments, but bestowed much decoration on them, ornamenting the ridges and tiles, and placing a series of *antefixæ*, or enriched front tiles, above the cornice along the sides of the building. This species of embellishment has been adopted in the church of St. Pancras, which structure also affords correct specimens of Grecian doors and windows. The latter, which are copied from those of the Temple of Minerva Polias, forming the western portion of the Erechtheium, are almost the sole extant type in Grecian architecture for such apertures. They are surrounded by a moulded architrave, and the jambs incline towards each other, so that the aperture of the window is somewhat narrower at the top than at bottom. This peculiarity may have arisen from the difficulty of procuring single stones for the lintel or upper architrave wide enough to extend over an aperture equal to the sill of the window; yet it may also have been adopted entirely as a matter of taste, with the view of both producing a contrast between the sloping outline of the windows, and the vertical lines of the walls and antæ; and an accordance with the tapering form of the columns. What serves to countenance this last idea is, that we find the same principle observed here as in the column itself, namely, that of restoring at the summit what had been lost by diminution upwards; for as the capital spreads out as wide as the base of the column, so is the upper horizontal lintel made as wide as the sill of the window, by means of a break towards the top of the side architraves (technically called a knee), so that the architrave expands there to the width of the sill.

The doorways of Grecian temples were made lofty and spacious, not only for the sake of rendering them important architectural features, but also because the light was admitted into the cella, or interior fane, usually of small dimensions compared with the general structure, through the entrance. The doorway is often inclined inwards, or contracted at the top; it has also a peculiar lintel or top-stone, with moulding running round it and meeting the ends of the architraves, and forming two elbows, thus:—



Greek lintel head, showing the manner in which the architrave moulding is formed round it.

The mouldings of the architraves are delicately formed, and decorated with ornaments, and a frieze and cornice supported on consoles are sometimes added. The decorations of the Erechtheium doorway are very rich, but the size of our cut precludes the possibility of giving them. This doorway is copied in the central doorway of St. Pancras Church. There was never more than one doorway within the portico or pronaos of a Greek temple. We have no example of the form and construction of a Greek door.

GREEK ARCHITECTURE. [Grecian Architecture.]

GREEK CHURCH. The Greek or Eastern Church is that part of Christendom which, founded, as is said, by St. Mark in Alexandria, about A.D. 60, separated from the Roman or Western Church in the 9th century. Even previously to that epoch there were several dissensions between the patriarchs of Constantinople and the popes of Rome, who claimed a supremacy over all the churches of Christendom; but the decided breach between the two churches dates from the year 862, under the patriarch Photius. The extension of the Greek Church by the conversion of the Bulgarians and some other Sclavonian nations excited the jealousy of the popes, who, moreover, having found a new support in the establishment of the Franko-Roman empire, began to act with more boldness against the emperors of Constantinople. Photius reproached the Western Church with the wanton addition of the word "Filioque" ("and the son") to the words "I believe in the Holy Ghost, the Lord and giver of life, who proceedeth from the Father," contained in the Nicene creed, and which he declared to be an antiscriptural doctrine. He reproached them, also, with having introduced several innovations unknown to the primitive Christian Church; as, for instance, the celibacy of priests, the repetition of the anointment, with the chrisma (confirmation), and the fastings on Saturdays; but he particularly inveighed against the assumption of the Roman bishops in considering themselves as the head of all Christendom, and treating the Greek patriarchs as subordinate to them. The final separation, however, of the Eastern from the Western Church did not take place till 1054, under the patriarch Michael Cerularius, who, in addition to the matters alleged by Photius, attacked the Latins for using unleavened bread at the communion, and for the profligacy of their clergy, &c., for which he was excommunicated by Pope Leo IX. The attempts at uniting the two churches, which were made either by the popes, in order to extend their dominion over the East, or by the emperors of Constantinople, who, being pressed by the Mohammedans, sought assistance from the Western powers, generally failed through the pride and interested motives of the leaders of both the parties. While Roman Catholicism was gradually developing itself under Gregorius VII. and his followers, as well as by the aid of the scholastic philosophy, the Greek Church remained stationary in its organisation as well as in its rules of doctrine, as laid down, 730, by John Damascenus.

The capture of Constantinople by the Latins in 1204, and the oppression of the Greeks during their sway, were calculated to widen the breach between the two churches. Michael II. Palæologos, who expelled the Latins from Constantinople in 1261, was inclined to effect a union with Rome; and his ambassador, with some Greek clergymen devoted to him, acknowledged the supremacy of the pope at the council of Lyon (1274), and to confirm this acknowledgment, a synod was convoked at Constantinople in 1277. But the bulk of the Greek Church being opposed to the measure, and the Pope Martin VI. having excommunicated the Emperor Michael, from political motives (1281), the separation from the Church of Rome was solemnly confirmed by the synods of Constantinople held in 1283 and 1285. The last attempt at uniting the two churches was made by the Emperor John VII. Palæologos, who, being driven to extremity by the Turks, came to Italy, and, at the council of Florence, in 1438, acknowledged the supremacy of the pope. The union was however not accepted either by the Greek clergy or by the people; but the constant efforts of Rome to attain this great object resulted in bringing to her many Greek churches in various parts of the world, and particularly in Hungary and Poland.

The Greek Church, like the Roman Catholic, acknowledges a double foundation of faith—the Bible, and tradition. Under this latter appellation it comprehends such doctrines as are supposed to have been verbally taught by the apostles, and which were confirmed by the Greek fathers of the Church, and by John Damascenus, as well as by the first seven Œcumenic councils of the Church (the 1st and 2nd of Nicæa, the 1st, 2nd, and 3rd of Constantinople, and those of Ephesus and Chalcedon). It forbids the patriarch and the synods to introduce any new dogma, but considers a full belief in those already established as indispensable to salvation. It maintains that the Holy Ghost proceeds only from the Father, differing in that point from the Roman Catholic church, as well as from all Protestant churches, which admit the proceeding of the Holy Ghost from the Father and the Son ("Filioque"). Like the Roman Catholic church, it admits seven sacraments: baptism; the chrisma; the communion, preceded by auricular confession; penitence; priesthood; matrimony; and extreme unction. But it differs from the Western church in the following points: 1. That baptism, in order entirely to remove original sin, should be performed by immersion of the body three times in water; and that the chrisma, which it considers as the completion of baptism, should be administered at the same time. 2. Although it admits the doctrine of transubstantiation, it prescribes the communion of two kinds, which is administered with leavened bread; and the wine, which is mixed with water, is not given from the cup as among the Protestants, but put by the priest with a small spoon into the mouth of the communicant. 3. It requires from the secular clergy, as a necessary condition for receiving ordination, marriage with a virgin; but a priest who loses his wife cannot marry again, nor can a person be ordained priest who has been married more than once, or who has married a widow. It allows laymen to contract marriage only three times, and is very strict in regard to degrees of consanguinity; and it also establishes, in addition to the connection by blood, a spiritual affinity between sponsor and god-child. 4. It admits no purgatory. Besides the above-mentioned important points, the Greek differs from the Roman Church in several other matters of small moment. Thus, for instance, it allows the anointing of the body with the chrisma, not only to persons threatened with death, but to all sick persons as a means for restoring their health and obtaining the pardon of their sins. Although it admits no purgatory, it is customary with many of its followers to give the deceased a written testimony from the priest of his religious conduct, in order thereby to facilitate his entrance into paradise. This, however, is evidently a custom transmitted from the ancient Greeks, and it must be considered as a practice rather connived at than prescribed by the Greek Church. The same Church admits no works of supererogation, neither does it acknowledge any vicar of Christ like the Pope of Rome. Having retained the Decalogue unmutilated, it forbids, conformably to the second commandment, all kinds of carved images; but it permits and encourages paintings representing the Deity, the Holy Virgin, and saints.

---

[*] The temple of Athena Alea, at Tegea, built about 383, B.C., by Scopas, had, in the interior, a Corinthian (κόσμος Κορίνθιος) imposed upon a Doric order. The exterior columns were Ionic. (Pausan., 'Arcad.,' c. 45.) In this passage the word κόσμος (kosmos) corresponds to the modern word Order.

The followers of the Eastern Church are no less zealous than the Roman Catholics in invoking saints, particularly the Holy Virgin, and in their veneration of relics. Their fasts are much more numerous and strict than those of the Roman Catholics. Besides Wednesday and Friday in every week, they have four great fasts in the year: Lent, or the fast of 40 days before Easter; another fast which lasts from Trinity day to the feast of St. Peter and Paul, 29th of June; a third, "to the mother of God," which continues from the 1st to the 15th of August; and a fourth beginning at St. Philip's day, on the 15th of November, and ending at Christmas.

During all this time they abstain not only from meat, but also from milk, butter, and eggs. The ritual of the Greek Church consists almost entirely of outward ceremonies, and preaching or religious instruction is scarcely ever used. In addition to the mass, which forms the most important part, the liturgy consists in reading several passages of the Scriptures and a repetition of creeds and prayers, which the officiating priest begins and which are responded by the congregation. Every congregation has a choir which sings psalms and hymns, but the congregation takes no part in them. Instrumental music is entirely excluded from divine service.

The Greek convents follow the strict rule of St. Basilius. The abbot of a Greek convent is called Hegumenos, and the abbess Hegumena; the abbots who superintend several convents have the title of Archimandrite, and rank next to bishops. All the high ecclesiastical dignities, as bishops, archbishops, and metropolitans, are chosen from the regular clergy; while the secular can rise only to the rank of Protopapas, which is only one degree higher than that of an ordinary priest.

The Greek Church under the Turkish dominion preserves almost entirely its ancient organisation. It is now governed by the patriarchs of Constantinople, Alexandria, Antioch, and Jerusalem, of whom the first, as the Œcumenic patriarch, presides over the general synods of Constantinople, which are composed of the above-mentioned patriarchs, several metropolitans and bishops, as well as twelve eminent Greek laymen. He exercises a supreme ecclesiastical authority over all the Greeks of the Ottoman empire, and is also acknowledged as the primate of their Church by the inhabitants of the Ionian Islands, and such of those under the dominion of Austria, who profess the Greek religion; but, except by confirming the appointment of bishops when elected by the clergy, and presiding at councils, he exercises no supremacy over the other patriarchs. Independent states professing the religion of the Greek church have almost uniformly their own ecclesiastical superior, as was the case with Georgia, Abkhasia, and Servia. In Russia, since the time of Peter the Great, the sovereign is the real head of the Church, and the patriarchal powers are exercised by a synod. In Greece a similar constitution has been adopted (it was only recognised after much negotiation by the patriarch of Constantinople in 1850); and now the archbishop of Athens is at the head of the national synod.

For an account of the festivals, ceremonies, liturgies, &c., see 'History of the Eastern Church,' by the Rev. John Mason Neale, M.A.

GREEK MUSIC. [Music, History of.]

GREEN. [Light.]

GREENHOUSE. A building in which small plants of a delicate or exotic character are raised, without being exposed to the variations or inclemencies of the atmosphere. The temperature must be regulated by the nature of the plants, and it may be obtained by the use of stoves, of hot air, or of hot-water pipes, or in the case of conservatories by surrounding the earth of the pit by manure, whose gradual combustion, in the process of decomposition, may give out the necessary quantity of warmth.

It is usual, in the construction of greenhouses, to make three of the vertical sides of glass, and to hang the frames so as to allow air to be admitted at will. The top is also made of glass, and partially moveable. Care must be taken to conduct the waters of condensation in such a manner as not to allow them to drip upon the plants; and all passage of moisture, through the capillary action of the ground, must be intercepted. As a rule, the opaque side, or wall, of a greenhouse should be towards the north.

GREENWICH OBSERVATORY. [Observatories.]

GREGORIAN KALENDAR. [Kalendar.]

GRENADE, properly called hand-grenade, is a shell or hollow ball of iron, 2½ inches in diameter, and about 3 lbs. in weight, which, being charged with powder and provided with a fuse, is thrown by the hand from the parapets into the ditch and covered-way when occupied by the besiegers; or from the covered-way into the trenches, when the latter approach within 25 yards of the crest of the glacis. Hand-grenades are especially useful in the defence of unflanked ditches, &c.

As soon as the composition in the fuse is consumed, the fire communicates with the powder, and the ball is burst in fragments.

Grenades were first used in 1594.

Grenades have been made of glass, either with a fuse, or with four or five nipples distributed over the surface of the grenade. Percussion caps are placed on these nipples, which are exploded by the blow of the shell falling on the ground, and cause the ignition of the charge.

GRENADIERS are the tallest and strongest men of a battalion; they are embodied in one company, which is disposed at the head of the battalion when in column, and on the right flank when in line.

In France, as early as the year 1667, four men, appointed during a siege to throw grenades into the covered way of a fortress, and to take the lead in an assault, were distributed in each company of that which was called the king's regiment (infantry); and three years afterwards these men were formed into a separate company: subsequently every regiment in the French service had a company or two companies of grenadiers, and the regiment of guards had three: they were considered as the *élite* of the soldiery, being men of tried steadiness and valour. In 1676, the king of France instituted a company of cavalry designated horse-grenadiers, whose duty it was to repair roads previously to a march of the household troops.

It is probable that men under the denomination of grenadiers formed part of an English army soon after the introduction of that class of soldiers into the French service; for, from a list of the commissioned officers of the army in 1684, it appears that most of the regiments had grenadier companies. A corps of grenadiers was also attached to each of the three troops of horse-guards; in 1693 these were formed into a troop, and in 1702 another troop was added.

The English foot-grenadiers were at first probably employed in duties similar to those of the corresponding troops in the French service: for, in a work on the English military discipline (1686), they are said to be provided with muskets, swords, pouches to carry grenades, and hatchets: with these last, after firing and throwing their grenades, they were to cut down obstacles in order to enable the troops to rush on the enemy.

The men in the first of the three regiments of foot-guards are now designated "Grenadier Guards," and the Scots Greys constitute a regiment of horse-grenadiers; in both of those regiments a high bearskin cap is worn: but the men forming the grenadier companies of regiments of the line wear the same kind of caps, and, except slight peculiarities in the ornaments of the coat and hat, they are clothed and armed like other infantry soldiers.

GROOM, in old English, meant a servant in some mean station, a lad or lacquey who was sent on errands: and is said, by Kilian, to be derived from the Flemish *grom*, a boy. It answered to the French *garçon*, or perhaps *gamin*. At present, in common life, groom means a servant especially attendant on the stable. Jamieson says the original word was *gom*, and that the letter *r* has been inserted only in English and Scotch. The German *brautigam* is the English bridegroom.

In higher life, groom is the denomination of several officers or servants of the royal household, mostly in the lord chamberlain's department: such as grooms in waiting, grooms of the great chamber, grooms of the privy chamber, groom of the robes or stole, and, in the lord steward's department, groom of the almonry.

There was formerly also, in the lord steward's department, a *groom-porter*, who is said to have succeeded to the office of master of the revels, then disused. His business was to see the king's lodging furnished with tables, chairs, stools, and firing; as also to provide cards, dice, &c., and to decide disputes arising at cards, dice, bowling, &c.

From allusions in some of Ben Jonson's and Chapman's plays, it appears that the groom-porter was formerly allowed to keep an open gambling-table at Christmas: it is mentioned as still existing in one of Lady Mary Wortley Montagu's eclogues:—

> "At the *groom-porter's* batter'd bullies play."
> *Thursday*, *Ecl.* 4, Dodsley's *Collect.*, i. 107.

This abuse was removed in the reign of George III. Bray, in his account of the Lord of Misrule, in the 'Archæologia,' vol. xviii., p. 317, says, George I. and II. played hazard in public on certain days, attended by the groom-porter. The appellation, however, is still kept up: the names of three groom-porters occur among the inferior servants in the present enumeration of Her Majesty's household.

GROUND-BASE, in music, a subject consisting of very few bars, adopted as a base, and continually repeated during the whole movement, while the upper part, or parts, proceed at liberty. That the composers of the 17th century were proud of displaying their patience and industry by writing on subjects of this kind, we have many proofs remaining, one whereof, a chaconne by Purcell, which is equally good as an example and as a composition, is given in Dr. Crotch's 'Specimens,' vol. ii. p. 91.

GROUND GRU. [Ice.]

GROUND TACKLE comprises anchor, cable, bitts, stoppers, windlass, and all the articles and appliances used in securing a ship at anchor.

Enough for our purpose has been said of the anchor under its proper head [Anchor], to which we refer.

That the whole subject claims attention, and is worthy of anxious investigation, may not only be gathered from a consideration of the disasters which have so lately strewn our coasts with wreck (too many of these wrecks arising from defects in ground tackle), but parliament has just received favourably the application from Sir J. Elphinstone for a select committee "to inquire into the manufacture of anchors and chain cables for the merchant service," and the motion was agreed to on the 2nd of February, 1860.

The writer remembers the time when the chain cable had not supplanted that of hemp. In those days, not half a century distant, the East Indiaman, the deeply-laden West Indiaman, the burdensome collier, and even the line-of-battle ship, were seen in that far-famed and dreaded roadstead, "the Downs," on the Kentish coast, plunging to the strain of a long scope of hempen and "coir" cables, driving onwards again through surge and surf to the point of mean tension, from which a huge sea occasionally hurled them; the *elasticity* of the cables acting like a spring against the sudden blow from a huge wave sufficient to sweep the decks and cause the ship to tremble. It is well to contrast this with the present system. At the time when the chain cable was merely an attractive experiment, the oldest pilots and seamen were of opinion that its rigidity would in bad weather tear the bows from a ship, even from the strongest. For years it was remarkable that until ships were strengthened for the purpose, the capsizing of the windlass [WINDLASS] was a circumstance of more frequent occurrence; and it was only when public attention was drawn by chain makers to the fact, that the weight of the submerged chain itself, hanging in a curve, in some measure modified the shock of a sudden tension, that the ship-owners consented to fit their ships with a certainly more compact and more manageable cable, such as we have in use at the present day. The liability of the old cables to be destroyed by chafing in rocky anchorage grounds, frequently occasioned the loss of shipping. The necessity of anchoring in such unfavourable places might occur several times in the course of a long voyage, and not only would danger be incurred on each occasion, but there was the risk of a ship being compelled, owing to the loss of anchors, to pursue her course destitute of the usual means of security. The action of the water upon hemp, and its being alternately exposed to the air and water, rendered in time the strongest cables rotten and insecure. The idea of substituting iron cables first occurred to M. Bougainville, who made a voyage round the world, an account of which was published in 1771. The idea was not taken up until 1808, when Mr. Slater, a surgeon in the navy, took out a patent for a chain-cable. Its merits were not much valued until Capt. Brown, who had made experiments with chain-cables which enabled him to form a just opinion of their advantages, published the results, and thus directed the attention of naval men to their superiority. The Admiralty soon after ordered them to be tried in the navy. In 1812, Mr. Brunton obtained a patent for further improvements; and after the war he enjoyed a *brevet* for importing chain-cables into France, but the advantages which he derived from it were so small that he relinquished his privilege.

Chain-cables are now furnished with bolts at the distance of 10 or 15 fathoms from each other, by withdrawing which a ship may slip her anchor in case of necessity with less trouble than was formerly required in cutting a strong hempen cable.

Chain-cables are of various kinds, but one general description of the mode of manufacture will suffice. The efficiency of a cable is dependent on two operations widely distinct, namely, the *forging* and the *testing*. For large chains a piece of iron bar, seldom larger than 2¼ inches diameter, is cut to the proper length for a link, and is shaped in cutting like *fig.* 1. It is also during the cutting, and by means of a powerful revolving disc, bent into the form *fig.* 2. It is then ready for the chain-smith, who is necessarily a well-skilled workman, who carefully welds the two ends together, introducing at the time the cast-iron stud, *fig.* 3, the complete link having the form in *fig.* 4; other links are shut on to this in the same manner, until the ponderous chain, often of about 12 tons weight, is ready for the next process,—that of testing. The perfect welding of the two ends of the bar, is by all respectable anchor-smiths made a subject of pecuniary interest to the workmen themselves, since a failure in a link under testing involves to them loss of time and expense in replacement.

1

2

3

4

5

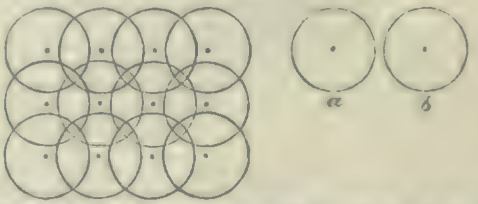
Small vessels use a chain without a stud, the links are variously proportioned to the thickness of the bar, the "short link" having the appearance of *fig.* 5.

From the great care bestowed on the manufacture of chain-cables by such houses as Wood & Co., of Saltney, the Tyne Works, and others eminent in the trade, it is doubtful if much improvement herein can be consistently hoped for. Such firms having their own testing-houses, usually give a certificate with their best chains; but the question arises as to *how far a second testing by public machines, such as at Liverpool, Sunderland, &c., is judicious?*

Professor Hodgkinson gives the tensile strength of wrought-iron as 24 tons to the square inch of section. Now the sectional are of a 2¼ inch chain will be 3·98 square inches, and therefore the maximum of breaking strain which such a chain is calculated to bear is about 95½ tons. But the question was strongly urged by Mr. Saxby in 1855 (see 'Nautical Mag.'), whether the amount of proof required by the government were not the cause of frequent failure of a chain from *over testing.* It is significant that Sir J. Elphinstone has just stated in the House of Commons, that in the public testing machines at Liverpool 82 *per cent.* of the chain-cables tried there had broken!

A few considerations on the operation of testing a metal may be useful. Especially should we investigate the probable effect of testing on the atoms [ATOMS] of which the iron (or metal) is composed. If we view the subject as a mere case of *strain* and *resistance*, we confine our scrutiny to a dangerous limit. Let us suppose it possible that the following figure represents a minute portion of a substance, say of wood or iron:—

Fig. 6.



Imagine the dots to be atoms enormously magnified. It is supposed that in all solids atoms are in approximation only, not in contact; that equilibrium is produced among these atoms by innate counteracting forces, attractive and repulsive. Let the circles surrounding the dots represent the limit of attraction for each atom while in equilibrium: suppose, for example, such dots are the atoms of a lancewood bow. If we cast arrows from it during, say, an hour, we shall on unstringing it find that if the arrows have been projected by means of *sudden jerks*, the bow will sooner recover its original shape than if such arrows had been thrown by a *slowly drawn* force; and moreover we shall find that the arrows in the former case will reach a more distant object than in the latter: hence we infer that the bow will bear a much greater strain with impunity in the first case than in the second. And thus it is with the testing of a chain-cable by the slow method in use. But to return to the bow; the common phrase "*losing its elasticity*" is very significant when applied to iron, which in this respect differs from wood, the one being ductile, the other not; hence a piece of wood bent so much as to draw its atoms farther apart than the imaginary circles in *fig.* 6 permit, or to separate its atoms beyond the sphere of each other's attraction, as shown at *a*, *b*, in *fig.* 6, becomes "broken," *unless* a restoration of position so sudden as to retard the re-arrangement which the disturbance of electric, or galvanic, or calorific agencies induce, *is possible*; and in the case of wrought-iron, this re-arrangement is supposed to commence when the tension amounts to about ten tons to the square inch of sectional area; and this can only take place at the cost of the metal's so-called "elasticity;" such changes in the iron depending upon a supposed polarity imparted to its atoms, by disturbance of electric currents made evident by the production of sensible magnetism.

The iron thus becomes comparatively "brittle," and consequently less able to resist even the proof-strain which, in the first instance, it may have borne with safety.

Does it not appear then that an iron chain cable, in being subjected to a *second* test, must become materially weakened? It is remarkable that, although we speak of iron becoming "permanently" stretched by a strain of upwards of 10 tons, such is merely *conditional*, because the judicious application of a red heat has, in the well-known process of *annealing*, the effect of restoring a state of equilibrium, a *fact bearing strongly upon a consideration of the very nature of electricity itself.* That the greatest strain which affects a ship's cable is in some measure favourable to the "restoration in position" of the molecules of the iron, may be understood from the following unexaggerated sketch. It is not the riding of a ship in a mere tide-way that usually tries a cable to the utmost; but it is the tremendous sudden jerks which a cable sustains when (as in *fig.* 7, c.) a ship is checked by her ground-tackle when on the very crest of a wave. The moment the wave has passed, the weight and "elasticity" of the chain (*if not destroyed by over-testing*), together with the weight of the metal in suspension from the shock, gives the ship an onward impulse which lessens the shock of the next wave (sailors believe in what they call "master-waves"); thus the chain has time to partially recover its atomic equilibrium: this may be seen in the altered angle at which the cable hangs from the hawse, as shown in *fig.* 7 *d.*

It would seem from the above remarks that, to lessen the dangers which at present affect ground tackle, so far as they result from the breaking (or "parting," as it is called) of the chain cable, the following points demand the deepest consideration:—

1. *Is it correct to test a chain to an amount far beyond* 10 *tons to the inch sectional area?*

2. *Should a chain ever be tested a second time?*

3. *Would not a suddenly acting test be preferable to a prolonged tension, at present sustained often for upwards of a quarter of an hour?*

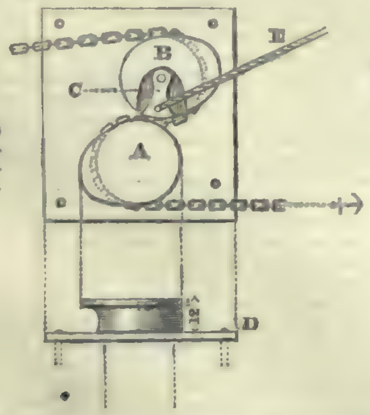
Fig. 7.

4. *Might not a chain after testing be annealed with advantage?*
5. Are chains of present dimensions strong enough?

But the subject of ground-tackle has other important phases. Question 5 suggests that there are times when a chain of sufficient strength to meet an emergency would be far beyond all limits of ordinary requirement, surpassing even the exigency figured above. For many ships are lost on a lèe shore, not so much from fairly riding when at anchor, but from the *shock felt in "bringing up"* on first letting go the anchor. Is it reasonable to suppose that a chain-cable manufactured with every possible care to bear a strain of (say) 95 tons, could resist the violent and sudden shock of a mass like a line-of-battle ship of 120 guns, absolutely weighing above 4000 tons, and *in a state of motion*, perhaps driving at the rate of 6 or 7 miles an hour, or upwards of 10 feet in a second?

We naturally, from this view of matters, turn to look in-board, in order to scrutinise the means used in *checking* a cable under such circumstances. *But there are none*—positively none! The cable is secured by turns round solid blocks of wood of huge scantling, or iron, and which are firmly attached to the framing of the ship itself. It may be supposed that *veering*, or letting go more chain, is the remedy, but it has its dangers also: for if once the chain resist the means of checking its progress, it rushes with increasing force until, from the ship acquiring velocity sternward, it is again suddenly checked by the clench of the cable round the foot of the mast, and like packthread it parts, to the most probable destruction of the ship. Another anchor may immediately be let go, but its chain too probably shares the same fate.

Fig. 8.

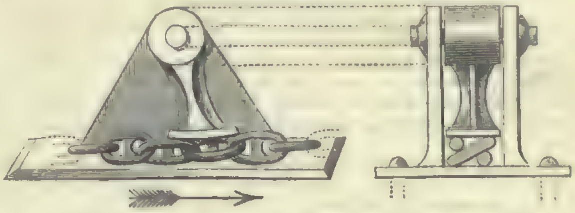


The stopper is shown as it appears while nipping the chain.

Stopper lanyard for securing chain.

A simple remedy has been proposed, and is at least worthy of consideration. If A and B (in *fig.* 8) be two well-secured bitt-heads (they need not be higher than 1 foot or 15 inches above the deck, as seen at D); the cable as brought in from the hawse-pipe passing round A, and also round B with a contrary flexure, would, from the friction exerted in letting go the anchor, be very much retarded. It is true that an extraordinary strain might, in this case also, cause the cable to *rush* out with violence; but if, in addition, there be inserted at C a patent excentric stopper, such as is figured above (and which has been in use for five years in some of the largest ships), the moment the officer of the deck might see fit he might cause to let go the lanyard, E, of the stopper, and allow the friction of the chain along the face of the purposely-lashed-open stopper *itself to close and nip the chain effectually*, gradually or not as he might please. The nature of this stopper admits of its being readily opened to veer away: indeed nothing yet known is likely to be so efficacious. [Windlass.] The stopper referred to is also peculiarly adapted for a position "chock-forward" near the hawse-pipe, for one placed there would prevent the fatal accidents which frequently happen from a capstan "running back" while weighing an anchor, in consequence of a sudden strain coming upon the cable. The stopper admits a chain or rope to pass through it in the direction of the arrow, but if the chain slip back it is immediately nipped by the excentric; and with a great improvement on every other method, inasmuch as it will be seen in *fig.* 9 the *curve rests on three links* of the chain, all others rest on one; and again in other stoppers a rushing chain can never be restrained *with certainty*, for in them, unless the link fall accurately into the "slot" prepared for it, it runs on, and even a *turn* in the chain itself may cause this.

Fig. 9.



(One side is removed to show the action upon the chain.)

It is to Captain Thomas Brown, of the merchant navy, that we owe great improvements, so far as they go; but until some such additions as above suggested are made to existing means for working ground-tackle, the gales upon our coasts will yearly diminish the profits of the shipowner and underwriter, and hundreds of lives will be lost in the most frightful of all calamities, the total shipwreck.

GROWING CROPS. [Emblements.]

GROYNE, a timber estacade, or masonry bank, carried out from the shore of a coast exposed to the action of a littoral current, for the purpose of arresting, as far as possible, the onward progress of the shingle transported by the current. If, indeed, the shingle were allowed to advance without impediment, it would itself, by the abrasion it would produce on the coast line, assist the encroachment of the sea; but the good effect of a series of groynes depends almost entirely upon their being placed so closely to one another that no counter eddy can be formed on the opposite side to the advance of the current.

Groynes are largely used upon the chalk shores of the British Channel, and upon the more yielding strata of the German Ocean. [Sea Defences.]

GRUS, the Crane, a constellation of the southern hemisphere, introduced by Bayer. It is situated between Eridanus and Sagittarius, a little below Piscis Australis. There are no stars of conspicuous brightness in this constellation.

GRUYERE. [Cheese.]

GUAIACENE. [Guaiacyl.]

GUAIACIC ACID. [Guaiacyl.]

GUAIACUM OFFICINA'LE, a tree, native of the West Indies, of which the wood and resin only are used in Britain, but the bark also on the continent, in medicine. The wood should be procured from the duramen, or central part of the trunk, as being the richest in the active principle. This wood should be very dense, heavier than water, of an obscure greenish fawn colour: but the recent fracture is yellowish, exhibiting an unequal cleavage, with a fatty shining appearance, if the specimen be good. The wood of the circumference is lighter, both in colour and weight, pale fawn, and opaque. In Guiana the wood of the *Dépterix odorata* (Tonka bean) is used under the name of guaiac-wood, which it greatly resembles; hence probably the statement of some writers, that the guaiac-tree is a native of America.

Genuine guaiac-wood is destitute of smell, but if rubbed, and still more if set on fire, it evolves an agreeable aromatic odour. If long chewed, the taste is peculiar, guttural, and bitterish. Trommsdorf obtained from 100 parts 26 parts of resin of guaiac: one pound gives two ounces of extract. The active principles are the resin and a peculiar extractive. Guaiac-wood is used in the form of raspings (chiefly obtained from the shops of turners who make blocks for ships of the lignum vitæ, as they term this wood); but this is a mixture of the wood of the external and of the internal layers, of variable strength and quality. The wood is less used than the resin. Guaiac-resin exudes spontaneously, or in consequence of incisions, and hardens on the bark. Resin obtained in this way is generally in spherical or long tear-shaped pieces. It is also procured more abundantly by cutting the stem in pieces of moderate length, boring a hole through it, then putting the one end in the fire, and collecting the resin, which flows from the opposite end, in calabashes. Another mode is to boil splints of the wood in salt and water: also, by digesting the rasped wood and bark in alcohol.

There are some slight differences in colour, transparency, and other points, according to the method of obtaining it; but these are of little consequence, provided no accidental or fraudulent admixture of other substances have occurred, such as pieces of wood and bark, sand, or amber. To purify it from these, it is commonly dissolved in proof spirit. By this means a larger quantity of resin is procured than was originally subjected to the solvent, owing to a hydrate being formed. Resin which has been so purified has lost nearly all acrimony; the resin is likewise adulterated with colophony; and it is said to be adulterated with the resin or gum of the manchineel-tree, a most culpable substitution, owing to its formidable powers.

According to Unverdorben, guaiac-resin consists of two distinct resins: the one is easily soluble in aqua ammoniæ, which the alcoholic solution of acetate of copper precipitates; the other forms with ammonia a tarry combination, which is soluble in six thousand parts of water, and which the alcoholic solution of acetate of copper does not precipitate.

The resin of guaiac becomes blue by continued exposure to the air, and also when in contact with many organic substances: many vegetable substances, particularly several containing gum and starch, turn the tincture of guaiac blue; a point of importance, from the similar effect of iodine on starchy substances.

The acrid taste of guaiac-resin is owing to a peculiar bitter acrid, so-called extractive (or *guaiacin*), which is contained in much greater quantity in the bark than the wood. It is to this principle, according to Buchner, that guaiac-resin is indebted for its medicinal powers.

Guaiac possesses the property of stimulating the system generally, causing increased vascular action, augmented heat of the body, and promotes the secretions of the skin and lungs; but in large doses it produces nausea, anxiety, abdominal pains, and stupor. It is not prized now so highly as on its introduction into European practice in the 16th century, when it bore a most extravagant price, four ducats being often given for a pound of the wood. It is, however, a useful agent in certain forms and stages of gout and rheumatism, and in some cutaneous diseases, especially when in the first set of disorders it is combined with ammonia, and in the latter with mercurials and diaphoretics or antimonials, as in Plummer's pills.

Its insolubility in watery menstrua is an obstacle to its easy administration, and even its alcoholic solutions are precipitated on the addition of water. It is generally made into an emulsion, or given in pills; but a soap may be formed by means of heated aqua potassæ, in which the resin is to be dissolved, then evaporated, and a soft consistent mass is obtained, which may be formed into pills or a bolus.

GUAIACYL ($C_{14}H_7O_4$), the theoretical base of the resin called guaiacum. If this resin is distilled, an oily liquid is obtained, which is regarded as a hydride of guaiacyl, $C_{14}H_7O_4+H$, although it has been named *pyroguaiacic acid.*

Another constituent of guaiacum resin is *guaiacic acid* ($C_{12}H_8O_6$), which crystallises in needles, and is freely soluble in water. By destructive distillation the resin also yields *guaiacene* ($C_{10}H_8O_2$), a light volatile oil, which absorbs oxygen from the air, and forms a crystalline compound.

GUANINE ($C_{10}N_5H_5O_2$), a compound discovered by Unger in guano. It resembles urea in its properties, forming crystallisable salts with hydrochloric, sulphuric, and nitric acids. It is a white powder, and insoluble in water. Its salts are all neutral or acid, none basic.

GUANO (from the Peruvian word *huanu,* which signifies dung) is the excrement of sea-fowl, and was used as a manure probably for ages before Peru was visited by the Spaniards. It is spoken of by Herrera in a work published at Madrid in 1601; by Garcilaso de la Vega, in his 'Memoriales Reales,' published at Lisbon in 1609; and by Ulloa in his 'Voyage.' Garcilaso de la Vega says that "in the time of the Incas there was so much vigilance in guarding these birds (the sea-fowl), that during the rearing season no person was allowed to visit the islands which they frequented, under pain of death, in order that they might not be frightened and driven away from their nests. Neither was it allowed to kill them at any time, either on or off the islands, under the same penalty. Each district or territory had a portion of these islands allotted to it." Mr. Thairlwall, of Richmond, Yorkshire, who has visited the western coast of South America, describes a small island, about three miles in circumference, in 13° 44′ S. lat., on which guano is deposited in a solid mass 200 feet in depth. The surface is coated over with a thick incrustation of almost pure muriate of ammonia; and when the bulk is disturbed, the ammonia given out is so strong as to affect respiration, and to cause an unpleasant sensation in the eyes. Peruvian guano is imported into England only by the agents of the Peruvian government, Messrs. A. Gibbs & Co. About the commencement of 1843 guano was discovered on the island of Ichaboe, about two miles and a half from the mainland of Africa, in 26° 13′ S. lat. and 14° 15′ E. long. The place soon attracted notice, and by the end of 1844 the whole of the guano had been carried away. As many as 350 ships have been anchored off the island at the same time. The guano was 35 to 38 feet in depth, and the deposit extended to a length of about 1100 feet, with an average width of 400 feet. Towards the close of 1844 another guano island (Malagas) was discovered at the entrance of Saldanha Bay. The guano covers an extent of about eight miles, and gradually increases in thickness from about 4 yards to 8 yards. It is obtained for shipment by a licence from the collector of customs at Cape Town. In October, 1845, a cargo of guano was brought to this country from Patagonia. It has been supposed that the excrement of the sea-fowl which swarm on some parts of the coast of Great Britain might be used as a fertiliser with the same results as Peruvian or African guano; but the quantity which could be collected is comparatively small, as the annual accumulation is in most cases washed away by the rains, and the valuable properties of that which remains are dissipated by the changeable nature of our climate. In South America and Africa the dryness of the climate allows the guano deposits of successive years to accumulate, and the heat of the sun produces a coating of the surface which preserves its virtue as a manure. The superiority of the Peruvian over the African and other guanos is owing chiefly to the greater dryness of the climate.

A guano has been found on the Koorya Moorya Islands off the southern coast of Arabia, and has been imported to some extent, but its composition is very inferior to that of the Peruvian in all that constitutes worth in a manure.

The value of guano is to be estimated according to the proportions which it contains of—1, ammonia; 2, phosphates; 3, organic matter. The results of a number of analyses of Peruvian and African guano show the following variations in their composition:—

	Peruvian.	African.
Water	12 to 15	25 to 30
Organic matter	50 to 60	25 to 30
containing	12 to 15 parts of ammonia	5 to 9 parts of ammonia
Phosphate of lime	15 to 25	25 to 30
Fixed salts	—	8 to 10

African guano had the largest proportion of soluble matter, and that from Peru is remarkable for the quantity of uric acid that it contains, an element which dissolves very slowly. African guano may therefore have acted with greater rapidity, but the effect of Peruvian is felt for a long period.

Good Peruvian guano sells now at 13*l.* per ton. The article is extensively adulterated, and instances have occurred in which the adulterated matter prevailed to the extent of 97 per cent. Umber, stone ground into a fine powder, various earths, old mortar, and partially decomposed saw-dust, are employed for this purpose. The mixture is moistened with putrid urine and re-dried. Even genuine guano differs so frequently in quality, that it is never advisable to purchase it without a satisfactory analysis. Purchasers are often deluded with false analyses, and those who deal only with those who profess to be importers are not always safe. Dr. Ure advises the farmer before he buys to obtain an analysis from a competent chemist, and then to cork up a sample in a bottle, and in the event of his crops disappointing reasonable expectation he is in a better position for obtaining satisfaction for any fraud which may have been practised upon him. Farmers' clubs might retain a respectable chemist at a salary on condition that he should perform analyses for the members at a moderate fee. This is what in effect was done by the Agricultural Chemistry Association of Scotland, and the consequence was that scarcely a single sample of adulterated guano was offered for sale in that country.

The easiest test of the purity of guano is its weight. It may vary from 69 to 73 lbs. a bushel, and the lighter the better, provided on throwing it into water some of it floats. If heavier than 73 lbs. per bushel, it has been adulterated with earth. The following are the common chemical tests of its genuineness, as given by Mr. Nesbitt:—

(1). Procure from any druggist a common wide-mouthed 6-oz. bottle, with a *solid* glass stopper. Let this bottle be filled with ordinary water, the stopper inserted, and the exterior well dried. The scales to be used ought to turn well with a couple of grains. In one pan of the scales place the bottle, and exactly counterpoise it in the other by shot, sand, or gravel. Remove the bottle from the scale, pour out two-thirds of the water, and put in 4 oz. avoirdupois of the guano to be tested. Agitate the bottle, adding now and then a little more water; let it rest a couple of minutes, and fill with water so that all the froth escapes from the bottle. Insert the stopper carefully, wipe dry, and place the bottle in the same scale from which it was taken. Add now to the counterpoised scale 1½ oz. avoirdupois and a fourpenny piece; and if the bottle prove the heavier, the guano is in all probability adulterated. (2.) Place 10 grains of the guano in a platinum capsule, which is held by the tongs in the flame of a spirit lamp for several minutes, until the greater part of the organic matter is burnt away. It is allowed to cool for a short time, and a few drops of a strong solution of nitrate of ammonia is added, to assist in consuming the carbon in the residue. The capsule is again gently heated (taking care to prevent its boiling over or losing any of the ash), until the moisture is quite evaporated. A full red heat must then be given it, when, if the guano be pure, the ash will be pearly white, and will not exceed 3½ grains in weight. If adulterated with sand, marl, &c., the ash will always be coloured, and will weigh more than 3½ grains. (3). Dissolve in a quart of water as much common salt as it will take up, and strain the solution. Pour a quantity of it into a saucer or basin, and sprinkle on the surface the guano to be tested. Good guano sinks almost immediately, leaving only a very slight scum. The adulterated leaves the light materials floating on the water. (4.) If chalk or ground limestone has been used in adulterating guano, it may be shown by pouring strong vinegar over a tea-spoonful of the sample placed in a wine-glass. On stirring, effervescence shows its presence. Genuine guano, under the same circumstances, merely allows the escape of a few air bubbles. We add here the method suggested by Dr. Cameron in his recently published lecture on agricultural chemistry, for the detection of spurious guano. By drying and burning, Peruvian guano should lose from 55 to 60 per cent. of its weight. Its ash should be white, and should dissolve readily, and without effervescence, in dilute muriatic acid, leaving insoluble residue, which should not amount to more than 2 per cent. of the weight of the guano. Mixed with quicklime it should give a strong ammoniacal odour. A bushel of guano if pure weighs almost exactly 70 lbs.; if adulterated with clay, marl, sand, &c., the weight will be materially increased, and so far as this test applies gross adulterations will be easily detected.

The great cost of guano has materially checked its consumption, and it will be seen from the following table how much during the past year its consumption has fallen off. The fact is, that at the price of 13*l.* per ton many other manures are cheaper.

The following is a table of the imports since its first introduction :—

Years.	Tons.	Years.	Tons.
1841	2,881	1851	243,014
1842	20,398	1852	129,889
1843	30,002	1853	123,166
1844	104,251	1854	235,111
1845	283,300	1855	305,061
1846	89,203	1856	200,000
1847	82,392	1857	288,362
1848	71,414	1858	353,541
1849	83,438	1859 (10 months)	73,647
1850	116,925		

The subject of the relative value of fertilising ingredients in guano, and in other manures, has been largely discussed. Professor Anderson of Glasgow, at a meeting of the Highland Society, stated the following figures to indicate, according to the authorities named, the value per ton of the principal ingredients as obtainable in guano :—

	Way.			Hodges.			Nesbit.			Anderson.		
	£	s.	d.	£	s.	d.	£	s.	d.	£	s.	d.
Ammonia	56	0	0	56	0	0	60	0	0	56	0	0
Insoluble phosphates	7	0	0	7	0	0	8	0	0	7	0	0
Soluble phosphates	32	18	0	25	0	0	24	0	0	28	0	0
Potash	30	16	0	20	0	0		..		20	0	0
Alkaline salts	1	0	0	1	0	0	1	0	0	1	0	0
Organic matters	1	0	0	0	10	0	1	0	0		..	

These are the prices at which these several ingredients are purchased in guano at present prices. Can they be procured elsewhere at a cheaper rate? The ammoniacal liquor of the gas works, after having been once distilled, can be obtained containing 20 per cent. of ammonia at a price which gives that substance at from 3*d.* to 3½*d.* per lb., or about 28*l.* per ton. The objection to its use is, that the ammonia exists there chiefly as carbonate, and in that state is peculiarly liable to loss by evaporation. It is clear, however, that if concentrated gas liquor were applied to the soil, the farmer could afford to lose one-third of it, and still have his ammonia cheaper than in the state of sulphate. The application should be of 2 to 3 cwts. per acre on grain crops, both alone and mixed with a certain quantity of bone ash, and the land should be made up in ridges, and the solution, diluted to a proper extent, poured into the bottom of the furrows, while the plough, immediately following the application, should be made to divide the ridge and cover the ammonia. This should be done several days before sowing, for it would not answer to put the seed near the strong ammoniacal fluid, and a few days should be allowed for it to disseminate itself through the soil. One hundredweight and a half of the ammoniacal fluid, and the same quantity of bone ash, might also be tried on turnips, and should these applications prove successful, it will be possible to make a mixture as good as Peruvian guano at a cost of not more than 8*l.* per ton.

Mr. Finnie, of Swanstone, has recently called attention to the existing wastefulness in the use of guano. His advice included the following particulars :—Government should investigate every source from which a supply of guano can be obtained; we should encourage manufacturers by making trial of other portable manures; we should turn our attention more than ever to the dung heap at home; and, lastly, instead of employing guano by itself as formerly, for turnips and barley, on the lighter and weaker description of soils, let farmers use along with it an admixture of other manures, such as bone meal, dissolved bones, or even guano of a secondary class; and for turnips and potatoes on the heavier character of soils, employ along with guano some other nitrogenous manure, such as rape dust, blood manure, &c.

Thus :—Superphosphate, along with farm-yard manure, is quite a sufficient substitute for guano for Swedes. Apply 3 cwt. per acre, along with 10 or 12 tons of dung. Nitrate of soda, 1 or 1½ cwt., is better applied to corn crops, if used in place of guano. 1½ or 2 cwt. of sulphate of ammonia per acre is a good dressing for an acre of wheat. If you can buy good soot at 6*d.* to 8*d.* a bushel, you can find no cheaper dressing than 40 bushels of that per acre. If you cannot get that, apply ½ cwt. of nitrate of soda and 1 cwt. of Peruvian guano per acre broadcast, in showery weather if possible.

On the application of guano to the soil, Mr. Nesbit gives the following instructions :—

(1.) Guano is best applied in damp or showery weather.

(2.) Guano should not generally be put on grass land in the spring later than April.

(3.) When guano is applied to arable land, it should immediately be mixed with the soil, either by harrowing or otherwise.

(4.) When wheat is sown very early in the autumn, a less than usual amount of guano must at that time be applied, and the rest in the spring. The wheat otherwise might become too luxuriant, and be injured by subsequent frosts.

(5.) Guano, and artificial manures in general, should be put on the land only in quantities sufficient for the particular crop intended to be grown, and not with the intention of assisting the succeeding one. Each crop should be separately manured.

(6.) Guano, before application, should be mixed with at least from five to six times its weight of ashes, charcoal, salt, or fine soil.

(7.) Guano should on no account be allowed to come in direct contact with the seed.

An artificial guano may be easily compounded by an admixture of the constituents of natural guano, all of which, with the exception of bone-dust, may be procured of any druggist. Professor Johnston gives the following recipe for an artificial manure which will produce an effect about equal to 1 cwt. of natural guano :—78¾ lbs. bone-dust, 25 lbs. sulphate of ammonia, 1¼ lb. of pearlash, 25 lbs. common salt, 2¼ lbs. dry sulphate of soda; total, 132¼ lbs. The following artificial substitute for guano has been successfully used, at the rate of 5 cwts. per acre :—

Bones, dissolved in spirits of salt instead of oil of vitriol		18¾ lbs.
Charcoal powder	about	18¾
Sulphate of ammonia (gas salt)	about	9½
Common salt	about	9½
Gypsum		9½
Wood ashes	about	46
Nitrate of soda (cubic petre)		28
Sulphate of soda (Glauber salts)		10
Sulphate of magnesia (Epsom salts)		10
		160 lbs.

Three or four cwts. of guano, which is the usual quantity applied one acre, have often proved equal in effect to fifteen tons of farm-yard dung. Mr. Lawes, an experienced agricultural chemist, gives the following table of the constituents of these two quantities :—

Four Cwts. of Guano contain	
Phosphate of lime	112 lbs.
Ammonia	54
Organic matter	171
Potash, soda	30
Fifteen Tons of Dung contain	
Phosphate of lime	100 lbs.
Ammonia	195
Organic matter	8505
Potash, soda, and silica	1335

Experiments have indeed been made, the results of which showed that 3 cwts. of good Peruvian guano were equal in their immediate effect to 20 tons of good farm-yard dung; but much is required to be known of the composition of a soil, and of the crops which it is to yield, before the exact value of any manure for that soil and crop can be fully settled; and this can only be ascertained by extensive experiments under every variety of local circumstances. The question may also arise, whether guano and other stimulating fertilisers do not exhaust the land while they produce great immediate results. They may, by supplying ingredients in which the soil is deficient, enable the plant so to use up others present in the land, that the soil shall be poorer after the crop has been removed than it was before the manure was applied. In this way it is that certain "artificial" fertilisers are called stimulating, and that farm-yard dung is alone a complete manure.

For various crops the guano answers best after vegetation has commenced; and it is useful in some cases to apportion the quantity intended to be used per acre into two or three portions for sowing at intervals, but the intervals most favourable are not fully determined. For small allotments or gardens it is often most convenient to use guano in a liquid state, in which case 4 lbs. of guano may be mixed with 12 gallons of water, and used after it has stood twelve hours, and the proportion per acre may be from a half to one cwt. of guano to 160 gallons of water.

GUARANINE ($C_{16}N_4H_{10}O_4$), a substance identical with theine and caffeine, and found in the *Guarana officinalis.* [Caffeine.]

GUARD is a detachment of troops appointed to watch a position to prevent surprise, or to take care of stores, baggage, &c.

GUARDIAN, one who has the care of a person and his property, who, by reason of his imbecility or want of understanding, is in law considered incapable of acting for his own interest. Guardians in the English law are appointed only to infants, though under the civil law they were also assigned to idiots, lunatics, women, and sometimes prodigals. The laws of England indeed provide for the protection of idiots and lunatics, but the rules relating to them will be more conveniently considered under those heads, and therefore we shall here confine our remarks to guardians of infants. The guardian under the civil law was either a tutor or a curator. [CURATOR.] Guardians were appointed either by the will of the father, by the disposition of the law, or by the magistrate; and accordingly, with reference to its origin, the guardianship was styled *testamentaria*, *legitima*, or *dativa*. The nature of guardianship under the civil law is fully explained in the 'System des Pandekten-Rechts' of Thibaut, i., p. 377.

The usual division of guardians, according to the English law, and therefore the most convenient order in which to explain their office, is:—1. Guardians by the common law. 2. Guardians by custom. 3. Guardians by statute.

I. Guardians by the common law were of four kinds: guardians in chivalry, in socage, by nature, and for nurture.

Guardianship in chivalry is now abolished by the statute of 12 Car. II., c. 24, which extinguished the onerous portions of the feudal system. This guardianship arose wholly out of the principles of tenure, and it could only take place where the estate vested in the infant by descent. All tenants by knights' service, being males under 21, or females under 14, at the ancestor's death, were liable to it; and it continued over males till 21, over females till 16 or marriage. It extended over the estate as well as the person of the infant, and entitled the lord to make sale of the marriage of the infant under the restriction of not making it a marriage of disparagement, and to levy forfeitures if the infant refused the marriage, or married, after tender of an alliance by the lord, against his consent. The lord was bound to maintain the infant, but subject to this obligation he was entitled to the profits of the estate for his own benefit. This guardianship, being considered more an interest in the guardian, than a trust for the ward, was saleable; and if not disposed of, passed at the lord's death to his personal representatives.

2. *Guardian in Socage.*—This also, like the former, is a consequence of tenure, and takes place only where lands of socage-tenure descend upon an infant under the age of 14. Upon attaining that age, the guardianship in socage ends, and the infant may appoint his own guardian. The title to this guardianship is in such of the infant's next of blood as cannot have the estate by descent in respect of which the guardianship arises, lest, it is said, the lamb should be delivered to the wolf to be devoured. This precaution springs perhaps from too great a mistrust of human nature, and it seems that in the early period of the Roman republic no such distinction was made. No provision upon the subject exists in the laws of the Twelve Tables—the lawgiver did not imagine that the life of the heir was in danger, though it was put in the hands of the person who would reap a benefit by his death. (Montesq., b. 19, c. 24.) And even at a subsequent period no such rule was known to the civil law; and indeed such a rule could have no place in the Roman system of succession. By the laws of Solon, no one could be a guardian who was to enjoy the estate of the ward after his death, and such it has been shown is the law of England with regard to guardians in socage. The laws of Scotland and the old laws of France prescribe a middle course: the estate is entrusted to the next in succession, because he is most interested in preserving it from waste, but he is excluded from the custody of the person of the ward. This is the principle upon which the Court of Chancery proceeds in its management of lunatics and their estates. [LUNACY.] The 'Code Civil' of France, b. 1, tit. x., ch. 1, 2, 3, has many provisions relating to guardianships, too numerous to mention here. The guardian in socage is entitled not only to the custody of the person and socage estates of the infant, but also to his hereditaments not lying in tenure, and even his copyhold estates, where no custom to the contrary exists in the manor of which they are held, and also his personal property. The guardianship in socage is regarded as a trust wholly for the infant's benefit, and is not saleable, or transmissible, but in the event of the death of the guardian the wardship devolves on the person next in degree of kindred to the infant, not being inheritable to him, and the guardian is accountable to the infant for the profits of his estate.

Guardianship in socage is, however, superseded both as to the person and estate of the infant, if the father appoints a guardian according to the statute, as will shortly be mentioned.

3. *Guardian by Nature.*—This species of guardianship has no connection with the rules of tenure. It extends only to the custody of the infant's person, and lasts till he attains 21. Any ancestor of the infant may be such a guardian, the first right being in the father, the next in the mother, and if they be dead the ancestor to whom the infant is heir has a right to the custody of his person. Until 14, it seems the guardian in socage is entitled to the custody of the person, and after that age the guardian by nature.

4. *Guardians for nurture* are the father and mother of the infant; in default of father or mother, the Ordinary, it is said, may appoint some person to take care of the infant's personal estate and to provide for his maintenance and education, though this has been doubted. This species of guardianship extends only to the age of 14, in males and females. Both these last descriptions of guardianship are also superseded by the appointment of a guardian by statute.

Where an infant is without a guardian the Court of Chancery has power to appoint one, and this jurisdiction seems to have vested in the king, in his Court of Chancery, as *Parens Patriæ*, upon the abolition of the Court of Wards. [CHANCELLOR.] And where a proper case exists for the jurisdiction of this court, it will, treating all guardians as trustees for their wards, interfere not only with the property of the infant, but also with the custody of his person, and will, in case of any misbehaviour, remove a guardian, however he may have been appointed or constituted, and will appoint a proper guardian to the infant in his room. Of this jurisdiction an instance is afforded by the case of the Duke of Beaufort *v.* Wellesley—where, the father being alive, Lord Eldon upon moral grounds deprived him of the custody of his children—and this power of the Court of Chancery is now firmly established. And though the infant may have elected and appointed a guardian, this will not exclude the jurisdiction of the Court of Chancery, but upon the case being brought before the court it will order an inquiry as to the fitness of the guardian appointed. All courts also have power to appoint a guardian *ad litem*, that is, to defend a prosecution or suit instituted by or against an infant. ('Co. Litt.,' 88 b, Hargr. note.)

II. *Guardians by Custom.*—By the custom of the city of London the guardianship of orphans under age and unmarried belongs to the city; and in many manors particular customs exist relating to the guardianship of infants; but in the absence of any such, the like rules prevail as before mentioned of guardians in socage.

III. *Guardians by Statute.*—At common law no person could appoint a guardian, because the law appointed one in every case. The statute 4 and 5 Phil. and Mary, c. 8, seems to have given some powers to the fathers of infants to appoint guardians; but guardians by statute are now appointed by virtue of 12 Ch. II., c. 24. Under this statute fathers, whether under age or of full age, may, by deed or will attested by two witnesses, appoint any person or persons (except Popish recusants) guardians of their unmarried children until they attain 21, or for any less period. A guardian appointed under this statute supersedes all other guardians, except those by the custom of London, or any city or corporate town in favour of which an exception is made, and is entitled to the custody of the infant's person, and his estate, real and personal. If two or more persons are appointed guardians under the provisions of this statute, the guardianship remains to the survivor. By the wording of the statute a *father* alone is empowered to appoint a guardian, and consequently, though the omission was probably unintentional, it has been decided that neither a mother, nor grandfather, nor any other relation, can make such an appointment. Neither can a father appoint a guardian to his natural child: but in all these cases the Court of Chancery will appoint the persons named to be guardians if they appear to be fit persons to exercise the trust reposed in them.

Guardians are rarely now appointed by infants themselves, the jurisdiction of the Court of Chancery providing far safer and more effectual means for the management and control of their property; and since in many cases the Court will interfere by petition without the institution of a suit, a cheap and speedy mode of procuring its interference is afforded. The guardian is considered as a trustee for his ward, and is accountable for the due management of the infant's property, and is answerable not only for fraud, but for negligence or omission.

Guardian of the Spiritualities is the person to whom the spiritual jurisdiction of any diocese is committed during the vacancy of the see.

Guardian of the Temporalities is he to whom the temporal jurisdiction and the profits of the see are committed during the like period.

The words guardian and warden are of the same signification: indeed, they were formerly used indifferently. Thus the warden of the Cinque Ports was styled guardian, or in the old French, gardeyn, and churchwardens, gardeyns del Eglise. The Welsh word qward is the same as the English guard.

GUELPHS and GHIBELLINES, the names of two great political parties which divided Italy and Germany during the middle ages, became first known as the watchwords of their respective adherents at the battle of Winsberg, in Suabia, between two rivals for the Imperial throne, Conrad, duke of Franconia, and Henry the Lion, duke of Saxony, of the house of Guelph, Welf, or Wölf. Welf, who was young Henry's uncle, fought on behalf of his nephew, and his name was the war cry of his followers; whilst those of Conrad took for their rallying word the name of Waiblingen, a town of Wurtemberg, and the patrimonial seat of the Hohenstaufen family, to which Conrad belonged. [CONRAD III. in BIOG. DIV.] In course of time the name of Guelphs was given to all who were disaffected to the Emperor, and that of Ghibellines (which the Italians had formed from the German Waiblingen) to the supporters of the Imperial authority; and as the popes, reviving their old rivalry with the empire, encouraged and supported the disaffected Guelphs, they became at last the leaders of that party, and the Italian cities were divided between the adherents of the popes and those of the emperors. The names of Guelphs and Ghibellines were not however generally adopted in Italy till the reign of Frederic II., when Italy was divided, as it were, into two camps; some cities, such as Florence, Milan, Bologna, ranging themselves on the Guelph side, while Pisa, Arezzo, Verona, and others, remained

Ghibelline. The Ghibellines adopted as a symbol a white rose or a red lily; the Guelphs chose the eagle, already the arms of the Guelph family. But in the long struggle that ensued many alternate changes took place in each city, where sometimes the Guelphs, and sometimes the Ghibellines, gained the upper hand. [Florence; Genoa, History of, in Geog. Div.] Most of the powerful nobles in Northern Italy, the Visconti, Doria, Della Scala, Pelavicino, were Ghibellines; the Anjou dynasty, which the popes had called to the throne of Naples, were the main support of the Guelphs. As the emperors, engrossed by their German affairs, neglected and dropped their hold upon Italy, the names of Guelph and Ghibelline lost their original meaning, and the struggle became one of personal or municipal ambition among the Italians themselves, the Ghibellines being for the most part animated by a spirit of aristocracy, the Guelphs professing to be favourers of a popular form of government. [Dante, in Biog. Div.] But even this distinction was often belied by facts, and the leaders of the Guelphs in some towns tyrannised over their countrymen; whilst in some instances, as at Genoa, the Ghibellines formed really the popular party. In the 15th century the names of Guelphs and Ghibellines had become a mere traditional shadow, and at last the popes themselves united with the emperor in extinguishing the independence of the Italian republics, without distinction of parties. (Sismondi, 'History of the Italian Republics;' Raumer, 'Geschichte der Hohenstaufen.)

The House of Guelph, originating in Italy, settled in Germany in the 11th century, and very shortly acquired large territorial possessions. From this family has proceeded both the lines of Brunswick-Oels and Luneburg; it gave emperors to Germany, dukes to Saxony, Carinthia, and Bavaria; one branch became also Dukes of Este in Italy, and the House of Hanover claims descent from both branches. [Brunswick, History of, in Geog. Div.; Este, in Biog. Div.]

GUERITE is the term applied in fortification to the projecting masonry sentry boxes to be seen in many old fortresses, at the salient angles of works on the top of the revetment. They are provided with loop-holes, so as to enable a few men in them thoroughly to command the foot of the escarp along the whole extent of the face. They have, however, the disadvantage of enabling an enemy the more easily to take up the prolongation of works to place his enfilade batteries, by giving well marked points at the extremities of the faces: they have, therefore, not been much used of late years.

GUILDS. [Municipal Corporations.]

GUILLOTINE, an instrument for the infliction of capital punishment, proposed to the National Assembly of France by Joseph Ignace Guillotin, a physician, a native of Xaintes, and a member of the Assembly; and which from him took its name. It was adopted by a decree of the 20th of March, 1792, and used for the first time on April 25th.

This instrument, under other names, had existed as a means of public execution long before, in Germany, Bohemia, Italy, Scotland, England, and even in Persia and India.

Crusius in his 'Annales Suevici,' fol. 1595-6, tom. ii., p. 296, says, 'Antiquis autem temporibus, in Germania etiam, decollatio non gladio fiebat, sed querno ligno, habente scindens acutissimè ferrum. Addit Widemannus, se vidisse tale instrumentum Hale in vetere Nosodocheo (Siechaus) priusquam id destrueretur: et hodiernum ibi ædificaretur. Efferebatur inde illa machina, si quis plectendus esset: supplicioque peracto, eodem referebatur."—" Postea usus gladii successit."

In German this instrument was called *der Planke der Deil* (the plank of wood), and in older language *Falbeil* (the falling hatchet). In Bohemia it was called *Hagec*, something akin to the plank. In Italy it was known by the name of *Mannaia*, and an engraving of it may be seen in 'Achillis Bocchii Bonon. Symbolicarum Questionum,' lib. v., 8vo., Bonon, 1555, p. 36. There is a very beautiful engraving of the German instrument in a representation of the beheading of the son of Titus Manlius, by Henry Aldegrevers, dated 1553. Evelyn, in his 'Memoirs,' vol. i., p. 170, states that he saw a similar instrument at Naples.

Pennecuik, in his 'Description of Tweeddale,' pp. 16, 17, speaking of the Regent Morton of Scotland, says: "This mighty earl, for the pleasure of the place and the salubrity of the air, designed here a noble recess and retirement from worldly business, but was prevented by his unfortunate and inexorable death, three years after, anno 1581, being accused, condemned, and executed by the *Maiden* at the Cross of Edinburgh, as art and part of the murder of King Henry, earl of Darnley, father to King James VI., which fatal instrument, at least the pattern thereof, the cruel Regent had brought from abroad to behead the Laird of Pennecuik of that ilk, who notwithstanding died in his bed, and the unfortunate earl was the first himself that handselled that merciless *Maiden*, who proved so soon after his own executioner."

In England, what has been since called the Guillotine was used only at Halifax in Yorkshire, and confined even there to the punishment of felonies committed within the forest of Hardwick. Its use at Halifax is traced as far back as the time of Edward III. It was in 1650 that the last malefactors there suffered by it. (Watson's 'Hist. of Halifax,' p. 214-239.)

Joseph Ignace Guillotin, who revived the use of this instrument, in France, is supposed, by many, to have perished at a later period of the Revolution, like the Regent Morton, by his own invention. But this is not correct. He died a natural death, 26th May, 1814, at the age of 76. ('Biogr. Universelle.')

GUINEA. [Money.]

GUITAR, a musical instrument which, in various shapes, may be traced to the remotest periods of antiquity. The word is derived from the Greek κιθάρα, and comes immediately to us through the French *Guitare*, though it is nearly the same in the Italian, Spanish, and German languages. The terms *Cittern* and *Gittern*, used by the old English poets, are but corruptions of the primitive word.

The English and French guitar of the last century was wide and thin in body, short in the neck, and strung with wire. The modern guitar, which is of the Spanish kind, and differing little from the lute, consists of a body from seventeen to eighteen inches in length, four in depth, and of a neck of about sixteen inches, the latter carrying a finger-board divided by seventeen frets. It has six strings, three being of silk covered with silvered wire, and three of catgut.

The compass of this elegant instrument is from E below the base staff, to A above the treble staff, including all the intermediate tones and semitones. The best and cheapest guitars are made in Germany, and may be purchased in London at a moderate price.

GUM is a proximate principle of vegetables, of more universal occurrence than any other secretion by plants. It is in reality the material generally prepared by them for their own growth and nourishment, and is at first always in a state of solution, in which condition it mostly remains so long as it is contained in the internal tissues of plants; but when it escapes to the exterior of the bark it frequently becomes thickened, and even solid and pulverisable. It is probable that it never escapes to the surface unless some wound of the bark has been made, either by disease, the punctures of insects, the agency of fungi, by the knife, or by the more rapid growth of the inner wood, producing by its distension a rupture of the bark. The escape of the gum termed *cerasin* from plum and cherry trees may always be regarded as an indication of unhealthiness; the immediate cause of escape is the presence of a small corkscrew-like fungus termed *Næmaspora crocea*.

Gum is known in commerce only in the solid state; the term is often erroneously applied to substances which are a mixture of gum with resins, and which are properly *gum-resins*, such as ammoniacum, asafœtida, and the like, and even to substances which contain no portion of gum, such as euphorbium.

Arranging the gums according to the facility with which they are acted upon by water, we have at one end of the list gum-acacia, or gum-arabic as it is most usually called, and at the other end gum-tragacanth. Gum-arabic forms a perfect solution with even cold water, and to this variety of gum the term *arabin* is given; gum-tragacanth on the other hand, though swelling up immensely when digested in water, and at first sight appearing to form a solution, does not really dissolve, but forms a thick mucilage, and to this modification of gum the term *bassorin* is applied. The derivation of the name arabin is obvious, that of bassorin is obtained from *bassora gum*, a variety of tragacanth that comes from Bassora, and which contains scarcely a trace of arabin. Other members of the series of true gums are mixtures in variable proportions of these two gum modifications.

Arabin ($C_{12}H_{11}O_{11}$) is colourless, tasteless, and inodorous. Specific gravity, from 1·3 to 1·5. It is uncrystallisable. Its solution slightly reddens litmus-paper, and rotates to the left a polarised ray. Dilute sulphuric acid converts it first into dextrin and then into grape-sugar; strong sulphuric acid carbonises it: nitric acid converts it into mucic and oxalic acids. It forms soluble compounds with the alkalies and alkaline earths. It is precipitated from solution by persalts of iron, proto-salts of mercury, and subsalts of lead. The reaction with persalt of iron is characteristic of arabin: if the solutions are strong, a brown gelatinous precipitate is formed, soluble with difficulty in boiling water; if the solutions are weak, a yellowish precipitate is produced only after the lapse of some time; thus one part of gum-arabic in 100 parts of water gives a precipitate with persulphate of iron after the mixture has stood for twenty-four hours.

Bassorin is soluble in dilute acids or alkalies, and by very long boiling even in water, but in each case it is probably converted into arabin. Like arabin it is insoluble in alcohol or ether, and is oxidised by nitric acid to mucic and oxalic acids. The presence of bassorin gives the peculiar mucilaginous or viscous consistence to the decoctions of linseed, quince-seed, marsh-mallow root, &c.

Most of the commercial gums are obtained by incisions made in the bark of several species of acacia growing in Arabia, India, Upper Egypt, Senegal, &c. The specimens differ considerably in colour, even when obtained from the same species. Genuine gum-arabic occurs in pieces from the size of a pea to that of a walnut, or larger, which are irregular in shape, or roundish or angular; either white, yellowish, or dark wine yellow; scarcely any odour; taste mawkish, glutinous. Sp. gr. 1·316 to 1·482. It breaks easily into small irregular pieces; fracture uneven, vitreous; dissolves almost completely in water; 100 parts of water at 212° of Fahr. take up 19 parts of gum. The solution is almost transparent when made with cold water. Gum, when in powder, is often adulterated with starch, the presence of which is detected by tincture of iodine; or when cold water is used for the solution of the gum, the starch will remain undissolved. The mucilage made with cold water is not only purer, but keeps better, and for all purposes for which it can be used is preferable to that made with warm water, which is the common method.

Gum is not very easily digested when taken alone, and will often pass through the stomach nearly unchanged, if not associated with some bitter or astringent principle. Hence the advantage of some bitter extractive or astringent principle, either in the grasses themselves or in other plants, such as *tormentil* or lesser *centaury*, interspersed in the pasture lands of cattle. (See Davy, 'Agricultural Chemistry;' or Sinclair, 'Hortus Gramineus Woburnensis.') This property, however, renders it demulcent in affections both of the throat and also of the intestines, by sheathing the membrane from air or the irritation of acrid secretions. Hence allowing a portion to dissolve slowly is often useful in common colds. Mucilage is also used to suspend many insoluble matters in water. Its agglutinating properties render it valuable in many of the arts.

GUM-RESINS are secretions of plants which are produced in the greatest quantity, and most perfectly elaborated, in warm countries. They are obtained chiefly from trees and shrubs of particular tribes of plants, rarely from herbaceous plants, except the large herbaceous *Umbelliferæ,* which yield the fœtid gum-resins. They either exude spontaneously, or are procured by incisions of the stem and branches. When they first escape to the surface they are fluid, and of a light colour, but gradually harden, and become of a deeper hue, either by the evaporation of some of their volatile oil, or by the absorption of oxygen from the air, and the conversion of the oil into a resin. Some remain in a semi-liquid, viscid state, such as sagapenum and galbanum, which are only pulverisable in winter. Most gum-resins possess a strong odour, which in many instances is disagreeable, such as that of asafœtida, with a warm acrid taste, and by application to the skin for any considerable time they cause redness and inflammation. Owing to their composition being a mixture of gum and resin, they are not completely soluble either in water or absolute alcohol, but are perfectly dissolved in proof-spirit, which is much employed to prepare tinctures of this class of substances. The gum being soluble in water is capable for a time of holding the resinous portion suspended in water, thereby forming an emulsion,—a state which permits of their administration, if used soon after being prepared; for by rest they separate. Many of them are soluble to a certain extent in acetic acid, especially when assisted by heat. The strong mineral acids char them and produce chemical changes. Many gum-resins are popularly termed balsams, a designation to which they have no title, as they do not contain benzoic acid.

Gum-resins are with difficulty soluble in the animal juices, yet, as they must be assimilated before they produce their characteristic effects, they require to be used for some time before the secretions of the body acquire their peculiar odour. They influence the secretory and excretory processes, which they rouse to continued action. They also act upon the skin as sudorifics, and more permanently than the volatile oils. They manifest their beneficial effects chiefly when the skin is cool, pale, and in a state of atony; and they can even check profuse perspiration, when this is caused by the lax state of the cutaneous tissues. They are likewise possessed of considerable antispasmodic powers, and hence are much used in nervous complaints. They greatly promote digestion when the stomach is feeble, owing to a defective supply of nervous energy. Their utility in the treatment of hysterical and other paroxysms is very much increased by administering them in a state which admits of ready solution in the gastric fluids; hence the acetous preparations of them are much more potent than any other form. They may be administered either by the mouth, or, in case of spasm closing the teeth, or the patient being refractory, in the form of clyster, the dose being doubled in the latter instance.

Gum-resins are likewise applied externally, owing to their rubefacient powers, in the form of liniments or plasters, in spasmodic and rheumatic affections, and also to assist in dispersing indolent tumours.

Gum-resins should be kept in cool well-closed places, to prevent the evaporation of their volatile principles.

GUMS AND GUM-TRADE. Professor Solly, in a paper on the subject of Gums, read before the Society of Arts, recommended to drug-brokers the adoption of a more exact classification than at present prevails, between gums, resins, and gum-resins. Dealers and brokers know very well what they mean; but they are not so precise as chemists in the nomenclature adopted. The distinctions recommended are as follow. *Gums* to comprise those natural vegetable exudations which soften or dissolve in water, and yield a more or less perfect mucilage, but which are wholly insoluble in spirit; *resins* to comprise those fusible and combustible vegetable substances which are quite insoluble in water, but which soften and dissolve in spirit, ether, or essential oil; and *gum-resins* to comprise those natural products which are intermediate in properties, and partake of the nature both of gums and resins, being partially and imperfectly soluble both in water and in spirit.

Different kinds of gum, limited and defined as above, are extensively used in the arts, especially in finishing and giving lustre to crape and silk goods, and in numerous processes of calico printing. One kind alone, *Gum Senegal,* has been imported by a single Liverpool firm to the value of 100,000*l.* in three years; and the export of gum from Alexandria has often reached 140,000*l.* per annum. The Cape colonists established a trade with the Kaffirs, a few years ago, for gum which was obtained from the *mimosa* tree, and which was sent to England for the use of calico printers, calenderers, envelope makers, &c.; the trade afterwards fell off, through the invention or discovery of *British gum*, presently to be described. The east and west shores of the Red Sea are the chief sources for *gum arabic* (which scarcely differs from gum senegal); from two to three hundred tons pass annually through the Custom House of Aden alone. Large quantities are collected by persons in the employ of the Egyptian government, and brought in caravans to Cairo to be warehoused; in recent years, the quantity has averaged about 20,000 packages of 78 lbs. each. The produce of Morocco is packed in very large leather sacks, and conveyed on the backs of camels and bullocks to the ports, where it is sold to English and French merchants; during the whole time, from the collecting to the sale, including the land journey, the natives live almost wholly on the gum, a few ounces being sufficient to support a man for twenty-four hours. A gum exuding from the *Macarung* or *Indica* in Travancore, is occasionally used for taking impressions of leaves, coins, medallions, &c.; when this gum is pure and carefully prepared, the transparent casts are as sharp as those of sulphur, without its brittleness.

The gums proper are most largely used in the stiffening of textile materials; the resins proper are, for the most part, used in the making of varnishes and lacquers, in dyeing, in paper-making, and in making sealing-wax. The gum-resins are mostly used in medicine. Many of these substances are of sufficient importance to occupy separate articles in this division of the Cyclopædia; while the general character of the uses of others can be inferred from the observations just made.

For some delicate processes in the arts, gum arabic and gum senegal require to be purified. The following is one mode, patented a few years ago, for effecting this:—A solution of purified sulphurous acid gas being prepared, the gum is dissolved in it, with exclusion of atmospheric air. The earthy and ligneous impurities fall to the bottom; the colouring matters combine with the gas; and the carbonic acid is driven off by the application of heat. Carbonate of baryta, or some other solidifiable base, is added; this combines with the sulphurous acid and forms a neutral salt. The solution is then filtered through a pure gelatinous hydrate of alumina; and is finally dried by heat, either in the open air or in vacuum pans.

Mention was made above of *British gum,* as a substance which has lessened the use of foreign gums in this country. According to an account given by Mr. Simmonds, a fire on one occasion broke out in a potato-starch manufactory in Dublin. The burning building was deluged with water by the fire-engines, and the starch was washed about in every direction. One of the workmen fell down, and had his clothes soaked with the calcined starch and water. He thought no more of it till the next morning; when, upon dressing himself, he found the sleeves of his coat, the legs of his trousers, and the linings of his pockets, glued up so that he could with difficulty open them. On revisiting the scene of the fire, he discovered that the glutinous properties were possessed by the potato starch; and by a few simple experiments, a discovery was completed which has resulted in large profits. Under the names of *British gum, dextrine,* and *gum-substitute,* a new substance appeared in commerce, and became largely employed in the arts. It is nearly equal to gum arabic in adhesiveness, less affected by climate, and less than one-fourth of the price. It forms the main ingredient in the adhesive composition for envelopes and postage-stamps. For the chemical qualities of this substance, see DEXTRINE.

It is not easy to state the quantity and value of gums, resins, and gum-resins imported into this country, and mostly used here in manufactures and in medicine. They are scattered about under so many headings in the official lists, and are entered under such different forms, that they can scarcely be recorded collectively. The Liverpool importation amounted, a few years ago, to 2200 tons annually, including the heavy items of turpentine, resin, caoutchouc, and gutta-percha; but the importation of the last two substances has since prodigiously increased. [CAOUTCHOUC; GUTTA-PERCHA.] Four of the most costly substances in the above list, those which present the most value in the smallest space, were imported into the United Kingdom in the following quantities and values in 1856:—

	Cwts.	£.
Gum copal	6,300	16,700
Gum arabic	70,900	120,800
Lac dye	11,000	37,300
Shell lac	14,800	34,700

Many varieties of gum are included in the official entry, Gum arabic.

GUN is a term now generally applied to the larger description of fire-arm, but as a description of the principal varieties of fire-arms, both large and small, with notices respecting the dates of their invention, is given under ARMS and ARTILLERY, and under CANNON is an account of the manufacture of great guns, we shall here supply a notice of the manufacture of the smaller kinds of fire-arms, to which the names of musket or musquet, fowling-piece, &c. are applied.

The rise of the gun manufacture in Birmingham, which is its principal seat in this country, appears to date from about the commencement of the 18th century. Hutton, in his 'History of Birmingham' (pp. 78, 79, of the edition of 1781), relates that, according to tradition, King William III. was once lamenting that guns were not manufactured in his own dominions, but that he was obliged to procure them, at great expense, and with greater difficulty, from Holland; when Sir Richard Newdegate, one of the members for the county, who happened to hear him, observed that genius resided in Warwickshire, and that he thought his constituents would answer his majesty's wishes. The king being pleased with the remark, the member posted to Birmingham, where the pattern was executed in such a manner as to give entire satisfaction. Large orders were immediately given, and these were so frequently repeated that, to quote Hutton's quaint expression, the manufacturers never lost their road. From notices in Macpherson's 'Annals of Commerce' it appears that about 1787 the manufacture was prosecuted with great activity for the supply of foreign markets, the manufacture of Birmingham guns for the African market being estimated to give employment to between four and five thousand persons. By one of the strange perversities of taste, of which many examples may be found in the history of manufactures, guns marked "London" were long preferred to those marked "Birmingham," notwithstanding the well-known fact that Birmingham was the chief seat of the manufacture. The Birmingham manufacturers were thus induced to stamp their goods as if made in London; and when, in 1813, a bill was brought into the House of Commons to compel every manufacturer of fire-arms to mark them with his real name and address, they took the alarm, petitioned against the bill, and instantly subscribed a large sum to defray the expense of opposing it, urging that they made the component parts of the London guns, which were, in fact, only put together and marked in the metropolis. The bill was defeated, and shortly afterwards the Birmingham gun-makers were allowed to erect a proof-house of their own, and to mark their guns, after being subjected to the proof required by the Board of Ordnance, with a distinguishing stamp. Holland, in the work referred to at the close of this article, gives some curious information respecting the extent of the gun-manufacture of Birmingham, both during the protracted war in which England was involved at the commencement of the present century, and more recently, when English artisans have been employed to meet the demands of foreign states. From his statements, founded upon authorised returns, it appears that more than two-thirds of the fire-arms made for the Board of Ordnance were supplied from Birmingham, and that the stands of arms fabricated there for the British government in the years 1812 and 1813 amounted respectively to 288,741 and 320,643. During the period of greatest activity it is said that the Birmingham manufacturers produced a musket per minute, which is not an extravagant assertion, seeing that, supposing the work to be carried on for sixteen hours every day in the year, Sundays excepted, the number produced at that rate would be 300,240, or rather under the number supplied to the government alone in 1813. The contract price at that time was 36*s*. a gun; but with the peace came a great falling off in the demand, which led many gunsmiths to abandon the trade, and caused a great reduction of price. In 1830 the Birmingham gun-makers contracted with the French government for the supply of 140,000 stands of arms at the price of about 28 francs, or rather under 23*s*. per gun, and even that price, Holland states, was considered liberal. It has been repeatedly stated by M'Culloch and others, that between the years 1804 and 1818 Birmingham supplied to government and the private trade nearly 5,000,000 fire-arms; and Barlow, quoting from authentic documents, shows that between 1803 and 1816, the number of fire-arms received and issued by the British government amounted to 3,227,716 muskets, 118,103 carbines, 27,895 rifles, and 203,266 pistols. In 1813 our allies alone were furnished with 500,000 muskets.

The most essential part of a gun is the *barrel*, or cylindrical iron tube, closed at one end, in which the explosion of the gunpowder is produced, and through which the ball or shot is projected. The interior of the barrel, which is technically called the bore, is in the musket a perfect and smooth cylinder, but the exterior is made slightly conical; that is, roughly proportionate at each point to the disruptive force of the gunpowder, thicker at the *breech*, or closed end, where this is greatest, and tapering to the *muzzle* where it is least. The very severe trials to which the barrel of a gun is exposed in use, and the fearful results which attend its bursting, render it in the highest degree important to use none but iron of good quality in the manufacture, and to work it in such a way as to render the chance of failure as remote as possible.

Military muskets generally, and the cheaper descriptions of other guns, have their barrels formed of tenacious soft iron, which is wrought or rolled into the form of flat bars, called *skelps*, each of which is sufficient to form a single barrel. The length of a skelp is usually about three feet, and the breadth about four inches at one end, where also it has increased thickness or substance to form the breech of the barrel, but gradually tapering to about two inches and a half at the other end, which is to form the muzzle. Until about the year 1811, skelps were usually manufactured by means of the forge-hammer; and as considerable skill was required to ensure the regular gradation from the thicker to the thinner end, the workmen employed in forging them were able to command good wages. In the above year, however, in consequence of a strike among the skelp-forgers for what was considered an exorbitant advance of wages, a method of fashioning them by rollers was introduced, it occurring to the inventor, according to Babbage's account, "that if the circumference of the rollers between which the bar-iron was rolled, were to be made equal to the length of a skelp, or of a musket barrel, and if also the groove in which the iron was compressed, instead of being of the same width and depth throughout (as in the ordinary manufacture of bar-iron by rolling), were cut gradually deeper and wider from a point on the rollers, until it returned to the same point, then the bar-iron passing between such rollers, instead of being uniform in width and thickness, would have the form of a skelp." The experiment succeeded, not only in effecting a great saving of labour, and rendering the manufacturers independent of the refractory workmen, but also in producing skelps of superior quality. "The pure metallic particles," according to Holland's account of this invention, for which a patent was obtained by a Staffordshire ironmaster named Bradley, "being compressed by the rollers both edgeways and flatways at the same time, cohere more closely together; nor are the skelps so liable to veins or flaws as those which are edged up in a less hot state under a forge-hammer." The barrels made of them are said also to turn clearer and sounder than those forged by hand.

In the old method of welding the skelps into barrels, the thicker end was first heated to redness, and then hammered upon a groove or hollow cavity in the anvil until the edges were turned up. A mandril being then inserted in the concavity between them, the edges were turned over and welded together by the hammer. By the repetition of the like process upon a length of two or three inches at a time, the skelp was gradually converted into a tube or barrel, each of the lengths thus separately welded being exposed to two or three welding operations, with alternating high and low heats, the latter being intended to correct defects occasioned by the former. Several attempts were made to substitute the action of machinery for this tedious and laborious process, in one of which, patented in 1811 by Messrs. James and Jones, and described by Holland, the power was applied by a series of automatic hammers. Little, however, was done in bringing any such process into operation until a combination was formed among the welders, similar to that above referred to among the skelp-forgers, and which, if successful, would have caused the completion of a large contract which was then being executed to be attended with a very heavy loss. A method which had been patented some years before by one of the contractors, but which had not then been brought into satisfactory operation, was resorted to under this difficulty, and the result was, that barrel-welding by rolling machinery soon, in a great measure, superseded the old process; and the manufacture of iron tubes of lighter character, suitable for gas or water pipes, by a similar process, was subsequently commenced. Babbage, whose account of the introduction of this process we have quoted, observes that the combining workmen were thus permanently reduced to a lower rate of wages, and that as the new method of welding was far less injurious to the texture of the iron than the old, in consequence of the iron being exposed only once, instead of three or four times, to the welding heat, the public derived advantage from the superiority as well as from the economy of the process. Babbage does not mention the name of the person to whom the introduction of this improvement is due; but Greener, in his account of the same circumstances, attributes it to the late Mr. Clive, who was an extensive manufacturer of iron for gun-barrels, and states that the jealous opposition of the trade to his innovation led the Birmingham gun-makers to combine not to use his iron.

The most recent and authentic account we have seen of the modern improved method of barrel-welding is that communicated by Mr. Lovell, director of the royal arms manufactory at Enfield Chase, to Dr. Ure's 'Dictionary of Arts, Manufactures, and Mines,' under the title 'Fire-Arms,' where this method is said to have entirely superseded that of skelp-welding by hand. From this article it appears that, instead of being formed of skelps forged nearly to the intended length of the barrel, barrels are now made from flat bars of thoroughly refined iron, cut by shears into slabs ten or twelve inches long, and weighing from ten to ten and a half pounds, or less, according to the kind of barrel to be made. "These slabs, after being cut from the bars, are heated, and, to adopt Mr. Lovell's language, 'bent in their whole length, by means of conveniently grooved bending rolls, until they assume the form of rough tubes,' their opposite edges being brought to meet without overlapping. These tubes are then laid upon the hearth of a reverberating furnace, and brought to a full welding heat; and as soon as the edges come to a semi-fluid state, they are taken out and passed between grooved rollers, the grooves of which are rather smaller than the exterior of the tube. By this means the tube is perfectly welded from end to end, and if the heat be properly managed, and the juncture kept clear of dirt and cinders, the iron will become perfectly homogeneous in every part, without any appearance of the seam where the edges come together. The tubes are repeatedly heated, and passed through gradually decreasing grooves in the rollers; and to preserve their tubular form and ensure regularity in the *bore*, or internal dimension, during the welding process, they are taken out of the furnace and applied to the rollers, by means of a mandril consisting of a long iron rod considerably smaller than the bore, but having at the end a short steel treblett made exactly the size that the barrel is intended to be. By a simple contrivance it is arranged that, while the tube is passing between the rollers, the treblett shall always be immediately between them, so as to keep the bore open. The adhesion of the hot metal to the surface of the rolls or rollers is sufficient to draw the tube off the mandril. By a succession of rollings the barrel is elongated to the required length, and brought down to the required degree of tenuity; and if there be any surplus metal, it is cut off from the muzzle end. Gun-barrels formed in this way are found to stand proof better than those wrought by hand, because the heat is more equalised, and, in consequence of the great elongation between the rollers, any imperfections in the original mass of iron are dispersed over a greater surface."

All the processes hitherto described relate to the manufacture of what are termed *plain* barrels; but some of the most curious operations in the gun-maker's art relate to the manufacture of the superior kind of barrel called *twisted*, of which there are many varieties. In all of these the material of which the barrel is composed is rolled or forged into narrow bars, about equal in thickness to the intended substance or thickness of the barrel, and varying in width from about three-eighths of an inch to an inch or more. One of these narrow rods or ribands of metal, being moderately heated to increase its pliancy, is wrapped spirally round a cylindrical mandril about the size of the bore of the intended barrel, in such a way as to form a tube, which may be slipped off the mandril at pleasure. As the rods are not usually made of sufficient length for one to form a barrel, several are usually joined end to end, those which form the breech being thicker than those at the muzzle end. In this state the barrel is a coil of metal somewhat resembling, on a large scale, the kind of spiral spring employed by bell-hangers as a check-spring. It is then heated to welding heat, and forged into a solid or continuous tube, partly by hammering upon a mandril, and partly by what is termed *jumping*, or striking the end of the barrel upon the floor, by which the edges of the helical or spiral rod are brought into very close contact, and eventually incorporated together. Many successive heats are, of course, necessary in this operation, and the welding proceeds only two or three inches at a time.

The manufacture of the numerous varieties of twisted barrel is very minutely described in Greener's works, entitled 'The Gun; or a Treatise on the various descriptions of small fire-arms,' and 'The Science of Gunnery, as applied to the use and construction of fire-arms,' especially in the first mentioned, which contains many curious details upon the various kinds of iron employed. From these it appears that considerable difficulty has arisen from the circumstance that, as the progress of science has enabled manufacturers to produce articles of common use of very inferior qualities of iron and steel, the common *scrap* iron and steel, which consists of fragments of such articles when broken or worn out, and which is much sought after by the makers of gun-barrel iron, is very inferior to what was procurable a few years since. Even horse-nails, that is to say, the nails employed for fixing horse-shoes, and which when worn out are collected with avidity as furnishing one of the best descriptions of scrap-iron, under the name of *horse-nail stubs*, are now difficult to be procured of the quality required for making gun-barrels, since many of those used in this country are now made of malleable cast-iron, and a few such mixed with others would spoil the iron for the purposes of the gunsmith. *Wire-twist* is the technical name given to an excellent kind of twisted barrel, which by some ignorant dealers is supposed to be really fabricated of wire. Such barrels are formed of very narrow rods of compound metal, composed of alternate bars of iron and steel forged into one body, and then rolled out to the requisite tenuity, when the edges of the rods, which are brought to the surface of the barrel, will, on the application of a corrosive liquor, which acts differently upon the two metals, present a fibrous or wiry appearance. In forming a barrel of such rods care is taken that the adjoining edges of the spiral be alternately composed of iron and steel, so that the pattern may have a uniform appearance, although the difficulty of welding is thereby increased. *Damascus* barrels, or rather such as are manufactured in this country under that name, are composed of similar metal, but the rods are twisted upon their own axes until their component fibres or laminæ have from twelve to fourteen turns in an inch, and the rods are thereby doubled in thickness and proportionately reduced in length. Two such rods are welded together side by side, their respective twists being reversed. Barrels made of rods of Damascus iron have a very pretty appearance; but, as Greener observes, the metal is considerably weakened by the excessive twisting of its fibres, on the same principle, though not to the same degree, as a rope is impaired by over-twisting. Of this point Greener gives illustrations in the results of numerous experiments made by him on the cohesive strength of various kinds of iron. *Stub* barrels are formed of horse-nail stubs, cleaned to brightness by friction in a machine, and mixed with fragments of steel, usually of old coach-springs cut up into little bits resembling the stubs. These stubs and scraps are wedged compactly into a hoop or ring, which holds them together while they are exposed to welding heat in a furnace, and welded into a compact mass called a *bloom*, which is drawn out by rollers into the narrow strips required for making twisted barrels. Greener states that the usual proportions of this compound metal are fifteen pounds of steel to twenty-five pounds of iron-stubs; but he thinks the proportion of steel might be increased with advantage. Attempts to make barrels of steel alone have frequently failed owing to its hardness. "It is not," he observes in 'The Gun,' "sufficiently tenacious of itself, from its fineness of grain, to resist the sudden explosion of gunpowder." He states that when steel barrels have been found to stand proof, their shooting powers have been found very great, a circumstance which affords encouragement to efforts for introducing them. Some makers have tried to make iron barrels with an inner tube or lining of steel; but this appears objectionable, because the two metals thus used, do not spring together, although when combined as in wire-twist and stub-iron they may be considered to act as one substance, uniting the hardness of steel with, and compensating for its brittleness by, the tenacity of the soft iron. These remarks were published in 1835, and in the second work above mentioned, published in 1841, Greener states that much progress had been made in the use of steel since 'The Gun' was published; and of late years steel has been much used in rifle barrels, especially in America, where most of the rifle barrels are made from the solid bar of steel bored out. The same thing is now proposed by Mr. Burton for the military rifles, the difficulty however lies in welding on the cone seat. *Stub Damascus* is a very beautiful kind of iron formed like the Damascus iron above described, but of stub-iron instead of wire-twist, but it is open to the same objection on the ground of over-twisting.

We may here refer to a paper communicated to the Society of Arts in 1825, and published in their 'Transactions,' vol. xliii. pp. 105-108, which contains an account of the process employed at Bombay in making gun-barrels and sword-blades in imitation of those made at Damascus; from which it appears that these barrels are manufactured of iron hoops, obtained from European and chiefly from British casks. The more they are corroded by rust, the more highly are they valued; and if they are not sufficiently oxidised they are exposed to moisture until they become so. Being cut into lengths of about twelve inches, they are formed into a pile an inch or an inch and a half high, the edges being laid straight, so as not to overlap each other, and a longer piece is so fitted as to return over each end, and hold the pile together while in the fire. After being heated the pile is drawn or forged out to a bar about an inch wide and one-third of an inch thick, which is doubled up in three or more lengths, welded together, and again drawn out as before, this operation being repeated three or four times according to the degree of fineness required. The bar is then heated, a small portion at a time, and hammered on the edge so as to flatten it out the contrary way to that of the stratification, by which operation the wire or vein is brought out on the face of the strap or riband of iron. "The barrel is then forged in the usual way, but," Captain Bagnold states, "much more *jumping* is used than in the English method, in order to render the twist finer." "The most careful workmen," he adds, "always made a practice of covering the part exposed to the fire with a lute composed of mud, clay, and the dung of cows or horses, in order to guard against any unnecessary oxidation of the metal. When the barrel is complete, the twist is raised by laying the barrel from one to five days either in vinegar or a solution of the sulphate of iron, until the twist is raised; this process is called the wire-twist." "To produce the *curl*," he further states, "the bars or straps are drawn out to bars about three-quarters of an inch square, and twisted, some to the right and others to the left; one of each sort are then welded together, doubled up and drawn out as before; and upon the experience of the workman, any intricacy of twist is produced by this drawing out, doubling, and twisting." This latter process, it will be observed, resembles that of English workmen, as also does a piece of trickery which Captain Bagnold mentions, consisting in rough-filing a common English barrel, and welding a strap of Damascus iron spirally round it, or applying several such straps longitudinally, and welding them on; a fraud which must be severely condemned as impairing the barrel in a similar way to the attempted union of iron and steel above alluded to. It is important to notice, that the native Indian artists never work with coal under any consideration, but use solely charcoal from light woods. Coal, from its always containing traces of sulphur, is highly injurious to the tenacity of the iron.

Greener describes many other varieties of gun-barrel iron than are mentioned above, but these need not be further noticed, except to remark that the inferior twisted barrels are usually formed of wider rods than the better sorts, and are consequently weaker from the necessarily oblique direction of the twist, and from the circumstance that large rods do not get so thoroughly rolled as small ones, as well as from the inferior quality of the metal itself. He also describes numerous ways, often very ingenious, in which frauds are committed by unprincipled gunmakers, to avoid not only the increased cost of the superior kinds of metal, but also the increased charges for labour in almost every department upon barrels of the best quality. In some cases a strip of inferior iron will even be introduced into the heart of rods or bars of Damascus iron, by which, owing to the different expansive powers of the two metals, the gun will be impaired more than by the diminution of strength and intrinsic value.

The great amount of welding required in twisted barrels requires a very large fire, and Greener states that several hours should be spent in forging inferior barrels before the fire can be brought to a fit state for those of the best quality. Hence, he considers, the London barrel-forgers do not attain such perfection in this operation as those of Birmingham, because they do not generally make the inferior barrels necessary to bring the fire into a good state. The junction of the several lengths of rod necessary to make a twisted barrel is often effected by cutting each off in a sloping direction, and leaving them to be joined in the general welding operation; but it is better to weld them together before the twisting is completed. After welding, the barrels are re-heated to a welding heat, a few inches at a time, and hammered in a groove to the required size. Sometimes they receive a subsequent hammer-hardening in like way, when cold; but though this improves them much, it is often neglected.

After welding, the barrels are very carefully examined, and if needful, straightened by a few blows of the hammer. Holland states that their soundness is tried also, by placing one end in a bucket of water, and sucking with the mouth at the other end, until the barrel is full of water, when, if there be any crack or flaw extending through the substance of the metal, it may be detected by the appearance of moisture on the outside. They are then bored in a machine with an angular plug of tempered steel [BORING INSTRUMENTS], which is caused to revolve rapidly within the barrel, a stream of cold water being directed upon the outside to check the heat generated by the excessive friction of the tool. Greener states that the barrels are not annealed for this purpose, as Dr. Ure has represented in the 'Dictionary of Arts.' The outside of the barrel needs also to be made smooth and even, which was formerly done by applying it to the surface of a large grindstone, the workman allowing the barrel to roll slowly through his hands, so as to present every part of the surface successively to the stone; but this process is now in a great measure superseded by turning in lathes, a method which claims great economy, as well as superiority in point of accuracy, and the advantage of doing away with a most unwholesome business, and one by no means unattended with danger. In a lathe it is easy to ensure the perfect concentricity of the inner and outer surfaces of the barrel, and the perfect rotundity of the exterior surface, whereas, under the old plan of grinding, the sides of the gun were often very unequal in thickness, one side being in some instances nearly twice as thick as the other. In all cases it is advisable to forge the barrels as nearly as possible to their intended dimensions, in order that as little as possible of the surface, which has been condensed by hammering, may have to be removed. After the first or rough boring the interior is fine-bored with an instrument having but one cutting angle, which is kept to its work by strips of soft wood attached beside it. Generally speaking, barrels are bored with a perfectly equal cylindrical bore; but some gun-makers prefer enlarging the bore a little towards the breech, under the idea that the consequent contraction of the muzzle will cause the shot to fly more closely. The breech end of the barrel is then tapped with a screw-thread, to receive the breech-plug, which closes it at that end, and forms the abutment for the explosive force of the powder, and in which, in many cases, is formed the chamber to hold the powder, and the narrow passage by which that chamber is connected with the touch-hole. The best form of this chamber, and of the connection with the touch-hole, is a matter upon which gun-makers differ widely.

The barrels are then ready for *proving*, which consists in firing them in a building in which their explosion can do no harm, with a charge four or five times as great as they will have to bear when in use. A great number of barrels are fired at once, by laying them upon a strong framework of wood, with their touch-holes downwards, and connected with a train of powder which is conducted outside the building, within which is laid a heap of sand to receive the bullets. Common barrels are allowed to lie twenty-four hours in the proof-house untouched, in order that, by the action of the nitre in the gunpowder, any crack or flaw may be rendered visible. They are then carefully examined, and such as show any defect, or have bulged with the explosion, are returned to be reforged, after which they must be proved again, while such as have stood the test satisfactorily are stamped with a distinguishing mark. Notwithstanding the strict regulations which require every barrel to be thus tested, Greener thinks that in many cases the proof-mark is forged, and states that sometimes a cheat is committed by welding unproved tubes on to pistol barrels which have been proved, so as to convert them into gun-barrels, for the sake of saving the difference of a few pence in the cost of proving.

Sporting guns are very often made with two barrels fixed side by side upon one stock. Such barrels are made separately, and have their adjacent sides filed flat in order that they may lie close together. They are secured together by ribs running between them from end to end, and filling up the spandril-shaped grooves formed by their contact. For general sporting Greener says that they should not be mounted with the bores perfectly parallel with each other, but slightly converging, so that their line of fire may meet at a given distance; but opinions differ as to the best inclination or degree of convergence.

The wooden *stocks* upon which the barrel or barrels are mounted is most commonly made of walnut-tree, though bird's-eye maple and a few other woods are occasionally used. This is fitted to the barrel so accurately as to leave as little as possible to depend upon the metal fastenings by which they are connected together. Great care should be taken to adapt the weight, length, and curvature of the stock to the person for whose use it is intended. Greener observes that it is very common to make the stocks of sporting guns too short and too crooked; and Colonel Hawker, in a passage quoted by Holland, says that "the length, bend, and casting of a stock must, of course, be fitted to the shooter, who should have his measure for them as carefully entered in his gunmaker's books as that for a suit of clothes on those of his tailor." "He has then," the colonel adds, "only to direct that his guns may be well balanced, to do which the maker will introduce lead in proportion to their weight; so that, on holding each of them flat on the left hand, with the end of the feather-spring about half an inch from the little finger, he will find a sufficient equilibrium to make the gun rest perfectly steady on the hand." When the shaping of the stock is completed, it is shod with steel for fowling-pieces and rifles and brass for muskets, the trigger-guard and other metallic fittings and ornaments are let into the wood, and every part is fitted with suitable screws and fastenings, after which the whole is taken to pieces; the woodwork is finished by staining and polishing, the metalwork is filed and blued, and the barrels are sent to be finished, which is done in various ways.

When intended to be bright externally, barrels are filed all over with smooth files, and then polished with a steel burnisher. Military muskets were formerly polished in this way, but the time and labour required to maintain the polish proved so harassing during service, that the Duke of Wellington, during the Peninsular war, dispensed with it, and allowed the muskets to be browned. Of the various methods of browning or staining barrels, of which every gun-maker has his own, we may notice two, in the first of which, described by Holland, the solution employed consists of half an ounce each of nitric acid and sweet spirits of nitre, one ounce of spirits of wine, two ounces of blue vitriol, and one ounce of tincture of steel. These ingredients are mixed, the vitriol being previously dissolved in sufficient water to make, with other fluids, a quart of mixture. The barrel, being first thoroughly cleaned from grease and dirt, and having the muzzle and vent stopped up with wood, is wetted all over with this mixture, applied with a sponge or rag, and then exposed to the air for twenty-four hours, after which it is rubbed with a hard brush to remove the oxide formed on the surface. These operations may, if requisite, be repeated two or three times, until the barrel becomes perfectly brown. It is then carefully brushed, wiped and immersed in boiling water which holds a quantity of alkaline matter in solution, in order that the further action of the acid mixture may be prevented. The barrel is then dried, rubbed smooth with a burnisher of hard wood, and heated to about the temperature of boiling water, after which it is coated with a varnish composed of spirits of wine, one quart; pulverised dragon's blood, three drachms; and bruised shell-lac, one ounce. When this is dry the barrel is finally rubbed with the burnisher to give it a smooth glossy face. The second method we shall allude to is called *smoke brown* or stain, and is recommended by Greener as one of the best preventives of fraud in the manufacture of twist barrels, since it brings out the grain or pattern in a way which, to say the least, it is not easy to imitate. For producing it, the barrels are anointed with a little vitriolic acid, which is washed off, and the surface rubbed dry. A forge fire is then lighted and blown up, with coals containing as much hydrogen gas and as little sulphur as possible. When the coals are burnt until they give out a clear white flame, without any black smoke, the barrels are passed gradually backwards and forwards through the flame until they are covered with a black sooty covering. They are then placed for eighteen hours in a damp cool cellar, by which the iron particles will become coated with a red rust, while the steel retains its original sooty coat. The rust and soot being brushed off with a brush of steel wire, the barrels are washed and polished with a linen cloth dipped in water and fine washed emery, by which the two metals become very distinct, the iron being dark and the steel bright and polished. After drying, the smoking is repeated, and the barrels are left in the cellar for twelve hours, and treated as before; and thus the process is repeated until the barrel becomes as dark as may be wished, the darkest colour attainable being a fine purple-black on the iron, with a copper tinge on the steel.

The progressive steps in the invention of the fire-lock, or that contrivance attached to the breech of a gun by which the powder in the touch-hole is ignited, are noticed under ARMS. The essential qualities of a gun-lock are, first, that it should work easily and efficiently, so that the force required to move the trigger and release the spring by which the hammer, or striking part of the lock, is moved, shall not be sufficient to interfere with accuracy of aim and rapidity of firing; secondly, that it should not be liable to go off at half-cock (a position in which the lock should always be kept until actually preparing to fire, and in which even the application of force to the trigger has no effect upon it), or in any other way accidentally; and thirdly, that when the piece is on full cock, the pulling of the trigger should cause the gun to fire with certainty. The delicate workmanship of modern locks, the manufacture of which forms a distinct trade, which is carried on chiefly at and in the neighbourhood of Wolverhampton, leaves nothing to be desired in efficiency and ease of working, while the ingenuity which has been devoted to this branch of mechanical science has provided numerous admirable plans for lessening the risk of accident by means of tumblers or other contrivances for securing those parts of the lock which might occasion danger by their accidental removal. Some such contrivances, to give a fair account of which would require too much space in this article, are illustrated by

Holland, and in Dr. Ure's 'Dictionary of Arts.' Until a comparatively recent period all military guns, and most of those used for sporting purposes, were made with flint-locks, in which the ignition of the priming-powder was effected by the sudden stroke of a wedge-shaped flint against a piece of steel, by which a stream of sparks was directed into the pan containing the priming; and the greater number of flints required for this use caused the cutting, or rather breaking, of them to be a considerable branch of industry. When the first attempt was made to substitute for this contrivance the use of a fulminating or detonating powder, which, being ignited by simple percussion, should set fire to the ordinary gunpowder in the touch-hole, we are not aware; but, according to the work just referred to, the first percussion-lock was invented by the Rev. Mr. Forsyth, of Belhelvie, in Scotland. The improvement has, however, led to alterations in the construction of gun-locks which, as Holland observes, are hardly inferior to that which took place on the substitution of the modern flint for the ancient fire-match. The pan which contained the priming-powder, and the cover which shielded it until the moment of preparing to fire, are rendered unnecessary, their place being supplied by a small upright nipple, the perforation of which coincides with, and forms a continuation of, the touch-hole of the barrel. The cock, or striking part of the lock, instead of carrying a clamp to hold the flint, becomes a simple hammer, with a snout adapted to fall exactly upon the top of the nipple. The fulminating substance is usually placed, for convenience, in a small copper capsule or cap, resembling a thimble in shape, which fits on to the nipple, and, if not blown to pieces by the explosion, is removed previous to reloading. The hammer is provided with a shield to prevent any fragments of the copper cap from flying against the face of the shooter. The great superiority of the percussion principle in safety and certainty of action led to its adoption, after experiments most decisive as to its superiority, especially in wet weather, over the flint-lock, both in the arms of the British and all Continental armies. A long article relating to the compounding and use of percussion-powders made with fulminate of mercury, which forms the base of most such compositions, is given under "Fulminates," in Dr. Ure's 'Dictionary of Arts.'

Rifled guns are described under Rifle.

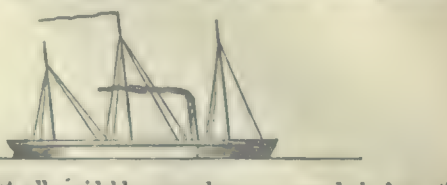
(Greener, *The Gun*, and *Treatise on Gunnery*; Holland, *Manufactures in Metal*, in Lardner's 'Cabinet Cyclopædia,' vol. ii., pp. 94-123; Barlow, *Treatise on Machinery and Manufactures*, in the 'Encyclopædia Metropolitana;' Dodd, *British Manufactures—Metals*, in Knight's 'Weekly Volume,' pp. 102-107; Dr. Ure, *Dictionary of Arts, Manufactures, and Mining*; Babbage, *Economy of Machinery and Manufactures*, sec. 362, 363.)

GUN-BOAT. This term has for many years been applied to small craft, mounting usually a single gun, when employed in the defence of coasts; and until very recently it indicated vessels of no peculiarity of construction, strength having been considered the main qualification, such as sufficient to sustain the continued working of a gun of light calibre.

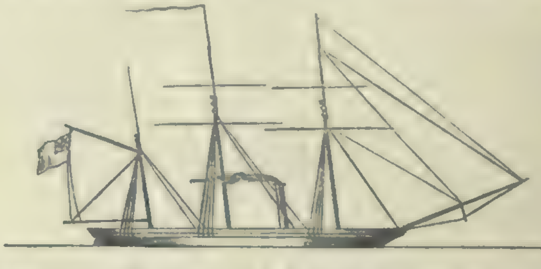
Change in naval tactics has, however, from improvements in projectiles, made such progress, that a totally new class of vessels has been called for. They are still further in request from the facilities afforded by progress in the art of propulsion. For a long period the collecting of a large number of guns in one ship had been thought the perfection of a floating battery; but the experience of the last Russian war established the importance of having a part of the armament of a fleet detached in small vessels, calculated from their light draught of water to navigate estuaries and parts of the coast which had hitherto been protected by their shallows.

Nor is it to this alone that the gun-boats of the present day owe their origin. The use of steam has so changed the features of naval warfare, that henceforward they will resemble more and more the evolutions of an army in the field; and, above all qualifications, *rapidity in manœuvring* must be paramount; and such is not so easily attained in large, long, heavily-armed ships, which, whatever may be the weight of metal thrown by their broadsides, cannot be turned to an opposite direction except within a considerable area of space and without the lapse of several minutes. Hence the attention of government has been directed to the building of the modern "gun-boat."

The ease with which a small vessel of about 100 feet length and 22 feet beam, having a light draught of about 6½ feet at the load water-line, could be manœuvred under the agency of steam as applied to the screw, even when armed with a heavy pivot-gun equal to the largest used on board the longest three-decker, was at once apparent to the Admiralty; and, accordingly, about 160 had been constructed by the beginning of 1860, 38 of them being actually on foreign service, some in the remotest parts of the globe; and before many months the number will in all exceed 200. These are generally armed with one 68-pounder gun of 95 cwt., so fitted as to be used either a-head or a-stern, or in any direction; while the vessel may be turned round almost in her own length, and in the lapse of a few seconds only. Some gun-boats have, in addition, a 32-pounder; others have two or four brass howitzers, 24-pounders. These vessels are propelled by high-pressure engines of 20, 40, or 60 horse-power. In these gun-boats, specially constructed for the purpose, and the crews of which are protected by shifting iron screen-plates from the effect of rifles, we possess a flotilla of formidable character; and as in any future naval contest these little vessels are destined evidently to play a conspicuous part, especially when armed with Armstrong's guns, we give a sketch as under. To prevent accidents from fouling the screw when dismasted, and also to prevent all avoidable encumbrance upon deck from the same cause, when in action, gun-boats are lightly rigged, have three short masts, and are fitted with gaff-sails.



A class of what may be called "despatch gun-boats," or, as they are officially called, "screw steam gun-vessels," and at present consisting of about 10 in number, are of larger dimensions, being, as the name would imply, built with capabilities for speed. They are nearly 200 feet long, and have about 30 feet beam, drawing upwards of 11 feet water, are of about 450 tons, and propelled by engines of 40, 80, and 160 horse-power. Some carry a single gun of 95 cwt., others two or four 24-pounder 12½ cwt. brass howitzers, in addition; they are rigged as three-masted two-topsail schooners. Several others, on improved principles, are now in course of building.



(Sir Howard Douglas, *On Naval Tactics*; *Screw Fleet of the Navy*, by Capt. E. P. Halsted, R.N.)

GUN-COTTON. *Pyroxylin.* If finely carded cotton be soaked for a short time in very strong nitric acid, and then washed and dried, it will be found to have acquired such powerfully explosive properties as to render it capable of being substituted for gunpowder. The cotton is not altered in appearance by this process, but its weight is increased to almost double. The reason of this increase in weight is that the elements of nitric acid (NO_5) replace, in the cotton, the elements of water (HO), the equivalent of nitric acid and of water being, as is well known, six to one; the increased weight is thus readily accounted for. The increase in weight, however, is not constant, but differs in an exact ratio with the strength of the nitric acid employed; the explosive and other properties of the resulting gun-cottons also differ considerably. In this way three, if not more, compounds may be prepared, in the first of which *three* equivalents of water, in the second *four*, and in the third *five* equivalents of water are respectively replaced by three, four, and five equivalents of nitric acid: or what is almost the same thing, only theoretically more correct, three, four, and five equivalents of hydrogen are replaced by equal numbers of equivalents of hyponitric acid (NO_4), the displaced hydrogen combining with the remaining equivalents of oxygen from the nitric acid.

Finely carded cotton has already been shown to be nearly pure cellulose [Cellulose], and, as the other varieties of cellulose are similarly acted upon by nitric acid, these explosive bodies may be viewed as nitro-substitution compounds of cellulose, and the three gun-cottons thus represented:—

Cellulose . . . . . $C_{24}H_{20}O_{20}$

No. 1. Trinitrocellulose . . . . $C_{24}\left\{\begin{matrix} H_{17} \\ (NO_4)_3 \end{matrix}\right\}O_{20}$

No. 2. Tetranitrocellulose . . . . $C_{24}\left\{\begin{matrix} H_{16} \\ (NO_4)_4 \end{matrix}\right\}O_{20}, HO$

No. 3. Pentanitrocellulose . . . $C_{24}\left\{\begin{matrix} H_{15} \\ (NO_4)_5 \end{matrix}\right\}O_{20}, 2HO$

No. 3 is very explosive, burning so rapidly when ignited, that the experiment may be performed on the palm of the hand without a sensible amount of heat being communicated to the flesh, or on a heap of gunpowder without danger of the latter being set fire to. This variety of gun-cotton is best prepared by digesting one part of cotton in fifteen parts of a mixture of equal volumes of nitric acid of sp. gr. 1·500, and of sulphuric acid of sp. gr. 1·845. The cotton must be completely immersed for about four or five minutes, and then plunged into a large quantity of cold water and washed till all trace of acid is removed: it is finally dried over a water-bath. So prepared, gun-cotton possesses an explosive power equal to three times its weight of gunpowder. Gun cotton, however, has not superseded the use of gunpowder for several reasons, the most fatal one being its liability to spontaneous ignition. From the greater rapidity of inflammation, gun-cotton also produces greater strain upon the gun, and hence necessitates increased thickness of metal. This quickness of explosion is increased to a remarkable extent by impregnating the gun-cotton with solution of chlorate of potash and then drying: on firing off a pistol loaded with two grains of gun-cotton so prepared, the barrel was shattered to pieces.

No. 1. gun-cotton is produced when acids of the strength commonly met with are used in the preparation. It is non-explosive and only partially soluble in ether containing a small per-centage of alcohol, such solution moreover leaves an opaque film on evaporation.

No. 2. is only moderately explosive, but readily dissolves in the mixture of ether and alcohol, the solution leaving on evaporation a perfectly transparent film. Hence this variety of gun-cotton is best fitted for the preparation of

Collodion.—This is the name of the solution just mentioned. It is very largely used by photographers, and is best prepared as follows:—Take of nitrate of potash, well powdered and dried, 600 grains, add to it a mixture of one and a half fluid drachms of water, and twelve fluid drachms of oil of vitriol: well stir the whole until it assumes a uniform pasty consistence, and then add in small tufts at a time, about forty grains of finely carded cotton. Let the cotton remain immersed for about ten minutes, and then wash and dry as already directed under explosive gun-cotton. If all the materials used in the process be pure, the resulting gun-cotton will be perfectly soluble in a mixture of seven parts of rectified ether, and one part of absolute alcohol, and moreover, the film of pyroxylin, left on the evaporation of the liquid from a small quantity of the collodion exposed on a glass plate, will be quite clear and transparent.

Pyroxylin balloons.—(*Collodion balloons.*)—A strong solution of collodion is made to flow evenly over the inner surface of a balloon-shaped flask, and evaporated to dryness by blowing dry air into the interior. By a little careful manipulation the pyroxylin may now be detached from the sides of the glass, and the whole drawn through the neck of the flask.

Pyroxylin balloons may be made use of for some pretty lecture illustrations with explosive gases. Thus they may be inflated with a mixture of two volumes of hydrogen, and one volume of oxygen, allowed to rise to the ceiling of a room, and there ignited. The ignition of the mixture is most conveniently effected by closing the neck of the balloon with a piece of thread impregnated with nitrate of potash, and setting fire to the thread immediately before the balloon leaves the hand.

GUN-METAL. [BRONZE.]

GUN-SHOT WOUNDS. Under this head writers on military surgery have usually considered not only all the injuries produced by cannon-balls, bullets, &c., striking against the body, but those which arise from the projection of stones, splinters of wood, and other substances broken off and thrown about by heavy balls, or by the explosion of shells, &c. We shall here include, however, only those produced by the shots themselves, because the others differ in no important degree from the more common contused wounds.

When a shot strikes the body it seldom produces much, if any immediate pain: a slight pricking sensation is felt, but the wounded man becomes aware of the injury only by his inability to move the part, or by feeling a little blood trickling over the adjacent sound skin. Whole limbs are known to have been shot off without the consciousness of the individual when in the heat of action. Sometimes when discovered the injury produces but little effect on the system: the courage and intellect remain unaffected; the pulse and respiration unaltered. Most frequently, however, if the injury be at all severe, it is followed by intense depression: the man becomes deadly pale, and is covered with profuse sweat; he trembles, and imagines death instantly at hand; he has shivering, nausea, and sickness, and remains unconscious of pain from his wound,—a sign always to be regarded with apprehension. These symptoms may soon subside if stimuli be given; but if they continue unabated for some hours they afford strong reason to fear that some important organ has been deeply injured. If the heart or the brain be struck, the man is often seen to leap from the ranks into the air and fall at once dead.

A part may suffer seriously from a shot without the skin being injured. These cases were long considered by surgeons (as they are still popularly) to be owing to the wind of the ball; that is, to the impulse of the air, set in motion and compressed by its swift passage. But the only portion of the air that could act on the body is that on one side of the ball, and this would not have much force outwards; besides, the small part of the atmosphere by the side of the ball being compressed in only one direction, while all around is free and moveable, could not acquire that degree of density necessary to produce such effects as were attributed to it. But still more certain proof that the air moved by the ball is altogether harmless, is afforded by numerous cases in which portions of dress are shot off without the parts beneath being injured. Dr. Thomson saw, after the battle of Waterloo, a man who had the tip of his nose carried off by a cannon-ball, without any further inconvenience; and another whose external ear was shot away, and his hearing not at all affected. Vacher also saw a man between whose legs a cannon-ball had passed, grazing one, and carrying off a piece of the trowsers over the other, but producing no bruise whatever. In the same manner, when a limb is shot off, the parts above the wound are but slightly injured. The real cause of this kind of injuries is, that the ball, whose force has perhaps been somewhat spent by the obstacles it has previously met with, strikes the part obliquely, and therefore with only a small part of its surface, so that the force applied is not sufficient to break through the skin, which is not only remarkably tough and elastic, but being placed on soft tissues which serve it as a kind of cushion, will yield considerably without tearing, and thus slant the ball off in another direction. The muscles and other tissues beneath it, however, being compressed between the ball and the bones, are more or less broken: there may be only a common bruise produced, but frequently the parts are found completely disorganised, broken up into a pulp with the blood effused from the vessels (often of considerable size) that have been ruptured, and sometimes even the adjacent bones are split and broken into fragments. If the ball has struck the head, or chest, or abdomen, the organs they contain may be ruptured, and give rise to such hæmorrhage or effusion of their contents as may be rapidly fatal. It was in such cases as these, when men were found lying dead in the field without any external mark of injury, that it was supposed they were suffocated by the ball passing rapidly before their mouths. If the ball penetrates the skin, a ragged opening with its edges inverted, and appearing somewhat smaller than the ball itself, is seen where it entered. The part around has a bluish or black colour from the bruise, and the cellular tissue in the track is seen black and dead. If it has struck a part perpendicularly, the ball will most likely enter into it straight; but if it have struck obliquely, it may be altogether slanted off, as in the preceding cases, or at least its course through the skin will be made more oblique, so that it will fall on the subjacent muscles at a still more acute angle than it did on the surface of the body. Its force, too, being somewhat expended, it will be the less likely to penetrate the dense fascia which usually covers them; and hence it is often found to have run for a considerable distance beneath the skin, till its force is completely spent, or till, meeting with a greater obstacle to its course onwards than outwards, it passes through the skin again, at a part considerably distant from that at which it entered. Some most remarkable cases of circuitous passages thus produced are recorded. Dr. Hennen mentions one in which the ball entered at the pomum Adami, ran completely round the neck, and was found close by the aperture at which it had penetrated; and another in which a ball struck the middle of a soldier's arm as he was climbing up a scaling-ladder, passed along the limb, over the back part of the chest, coursed along the abdominal muscles, dipped deep in the buttock, and presented at about the middle of the thigh, on the opposite side to that which it first struck. Sir C. Bell saw two cases in each of which there was one hole in the back, and another above the breast, so that externally they looked almost exactly alike; but in one case the ball, having struck obliquely, went up over the shoulder, and thence down to the breast; while in the other it had struck perpendicularly, and had gone straight through the chest. If the ball should penetrate the muscles, each layer that it meets with will render its course more oblique, till striking on the bone it may run for some distance along its surface. If it strikes very obliquely against the walls of a cavity, as the head, chest, or abdomen, its force may be so much expended in passing through them, that it may run for some distance along their concave internal surface, unable to penetrate the organs contained in them, as in cases mentioned by Dr. Hennen, where balls coursed between the peritoneum and intestines, and in one instance half round the chest between the lung and the concave surface of the walls. Similar cases are seen when the ball, striking very obliquely, does not penetrate at all, but runs for some way, even on a concave surface, between the dress and the skin, which it marks by only a slight graze. In these long or circuitous tracks, if the ball have run deep, there will be nothing to indicate the situation at which it has stopped; but when it has passed near the skin, its course will be marked by a dull bluish or dusky line, or a slight wheal. If it has passed directly into a limb, the most common situation for it to be found in is immediately beneath the skin on the opposite side; if it strike a bone, it is more likely to be arrested by its cancellous than by its compact tissue: often on passing through either its further course is prevented by the tough resisting tissue of ligaments. In almost all cases in which the ball has penetrated without passing through any part of the body, some foreign substance will be found in the track of the wound; either the shot alone, or with it portions of clothing, of the contents of the pockets, or cartridge boxes, or even (as in cases given by Dr. Hennen) of the bones of some other person whom the ball had before struck and brought along with it. Sometimes the portion of clothing carried before the ball is not perforated, but driven inwards in the form of a cul-de-sac, which may be drawn out again with the ball in it. Such a case is related where, in an attempt at suicide, a man fired a pistol close by the side of his head; the ball passed some depth into the brain, carrying the side of his night-cap before it, so that on taking it off the portion forced into the skull drew out the ball.

When the ball passes quite through the part, the aperture by which it makes its exit has characters just the reverse of those which we have mentioned as belonging to that by which it entered. Its edges are everted; it looks somewhat larger than the ball, and is less bruised. In these cases no foreign body may be found in the track of the wound, which is generally less circuitous than in the preceding class. Sometimes the ball is split by striking against the sharp edge of a bone, or obliquely on its surface; and then, while one piece passes out the other may run in any other direction among the tissues, where its presence is not likely to be suspected.

Lastly, a part of the surface, or of the whole substance of a limb, or of the trunk, may be completely shot off, either by one large ball, or by a whole charge of small shot. The surface thus left is uneven, ragged, and bruised; the vessels and nerves lie exposed, or hanging out; the bone protrudes, and is often split up, even to the next joint.

In all cases in which the ball has penetrated, the parts with which it has come in contact are so much injured that their vitality is destroyed, and sloughing to a greater or less depth ensues; to a greater distance around also all the tissues are severely bruised. The part divided presents a torn uneven surface; the vessels roughly rent across generally contract and close so that but little blood is lost at first; if a nerve be divided, unusual pain is produced, and the part is paralysed; if a bone be struck, it splinters, especially in the longitudinal direction, and is besides so shaken that death ensues in it, as in the softer tissues: after penetrating part of a bone, the ball often loses so much of its power that it remains firmly impacted in the medullary canal. If any of the cavities be penetrated, it is indicated by effusion of their contents, and other peculiar symptoms, as in the lungs by spitting up of frothy blood, extreme dyspnœa, air passing through the wound, and sometimes emphysema; in the abdomen, by protrusion of the viscera, passage of bile, fæcal matter, &c., into the cavity, producing at first extreme depression, followed by intense peritonitis.

The first process for the repair of the injury which gun-shots have occasioned is the separation of the slough or dead portion around the track of the ball. As in similar cases from common causes, the inflammation necessary for this purpose supervenes but slowly, though when established it is very intense, accompanied with great swelling, heat and pain of all the surrounding parts, and severe constitutional disturbance, fever, sleeplessness, disordered stomach, &c. As the slough separates and protrudes at the orifices of the wound, these (when double) present appearances just the reverse of those which they had when first made; that at which the ball entered (then the smallest) is now the largest, its edges are wide open, and it is generally filled with a large piece of sloughed tissue hanging from it, like tow dipped in pus; while that at which the ball passed out is contracting, or has been already healed by the first intention. This difference depends on the ball having lost much of its velocity in passing through the several tissues: hence the part last traversed is less bruised or destroyed; and if, as is often the case, the ball has been flattened in its course, it may have passed out with its sharp edge forwards, and given the latter part of the track so much the character of a common penetrating wound, that it might heal by the first intention. The constitutional symptoms change when suppuration is fairly established, the surrounding inflammation is lessened, the fever subsides, and in slight injuries the health may seem but little affected. In more severe ones, where, with considerable loss of substance, a very copious suppuration occurs, or where it involves some important tissue, as a joint or bone, &c., hectic fever supervenes, with debility, a small rapid pulse, speedy emaciation, copious night-sweats, diarrhœa, &c. A chief danger accompanying the separation of the slough is, that some of the large vessels, which, when torn by the ball, did not bleed much, if at all, may now ulcerate, and produce severe hæmorrhage; but if this be avoided, the further progress of the wound presents nothing that could distinguish it from one of the same extent produced by any penetrating instrument, and in process of being filled up by granulations.

Gun-shot wounds partake of the natures at once of penetrating, lacerating, and contused wounds, and they present the characters of all these in an extreme degree of intensity, from the velocity with which the ball, ill fitted by its shape for penetrating, has been propelled. The general rules of treatment must, however, be the same as for similar injuries from common causes; but it will be advisable here to notice a few points peculiar to this class alone, and to point out what, after long discussions, are now the most generally received rules of practice.

The extraction of the ball and other foreign substances, though its necessity has been very much exaggerated, is first to be considered. If, on examination of the wound (which should be made as much as possible with the finger), the ball and the substance it has carried in with it be felt tolerably moveable, and in a part where forceps can be easily applied, they should certainly be at once extracted; and sometimes, though very rarely, it may be advisable even to dilate the wound by incisions along its sides for this purpose. No violent attempts should ever be made at first to accomplish the removal; for as the walls of the wound slough and suppurate, the track will become larger, and they may then either fall out or be easily displaced; or they may sink down, and, presenting a dependent part, may be taken out after merely dividing the skin over them; or they may become imbedded in the surrounding tissues, and as the irritation at first produced subsides, the adhesive inflammation may form a loose sac around, in which they may lie for years, without producing any further inconvenience.

It has been already said that the ball may pass through a part, and lodge just beneath the skin of the opposite side, or that, after a circuitous course, it may be found under the skin at a distance. In either case, if it can be felt, even at the distance of an inch below the surface, it should be cut down upon and removed. If it strike against a bone, it may lodge in it superficially, and may then be displaced with the forceps or with the end of a scoop, or, if more deeply fixed, with a bullet-screw. If it pass through its wall into the cancellous texture, many surgeons recommend that the bone should be cut down upon, and a trephine applied over the ball, so as to cut out a piece of bone sufficiently large to draw it through. If the ball or other substances be not extracted at first, and remain fixed after the sloughing and suppuration, no further attempt to remove them should be made till the inflammation that has supervened is fairly subdued: then, if much irritation continues to be excited, if abscesses form about its track, and much constitutional disturbance is produced, it may be necessary to use every effort to find out their seat, and if possible remove them; but if still impracticable, and amputation cannot be performed, or is not deemed advisable, the future treatment must consist in supporting the patient by tonic and anodyne medicines, and by the mildest antiphlogistic local applications.

Whether the ball be extracted or not, the simplest possible dressings should be at first applied; a piece of linen spread with some mild ointment, fixed on lightly by strips of adhesive plaster, and covered by a rag kept constantly moist with cold water, are the best and most comfortable applications. Tight bandages, stimulating and heating ointments, &c., are especially injurious. It may be frequently advisable to bleed the patient immediately, or soon after the accident; and aperient medicine should always be given, and a mild antiphlogistic diet strictly enjoined. After three or four days, when suppuration is established, the cold application will probably cease to be agreeable to the patient, and then it should exchanged for some warm emollient poultice, or lint dipped in warm water or spongio-piline; and the constitutional disorder altering with the condition of the sore, the reducing remedies may be laid aside, and soon replaced by mild tonics, a nutritious diet, &c.

The question of amputation, when that operation is applicable, must be decided as in common cases by the character of each; no general rule can be given, except that, *cæteris paribus,* it will be advisable in many cases in military practice, in which in civil practice it would be scarcely justifiable. If the difficulty of removal from the field to any permanent hospital, the insufficiency of accommodation and nursing, which must be experienced when large numbers are simultaneously wounded, the badness of the air to which they will probably be exposed in crowded barracks, and other circumstances inseparable from the movements and arrangements of large military or naval forces, be considered, it will be evident that it would be advantageous to convert a severe wound, contused and lacerated, which even under the most favourable circumstances would be uncertain and most tedious in its progress, into a clean incised one like that of an amputation, in which danger from bleeding may be lessened and which will require far less attention than the other. As to the long-debated question, at what time amputation should be performed, it is now agreed, that the best period is as soon as possible after the patient has recovered from the immediate depressing effects which often follow the reception of the wound.

Wounds of the head, chest, and abdomen must be treated as in common cases: if the ball be lodged in these cavities, it will be improper to use more than the most gentle means to extract it; and if in the abdomen, it will generally be quite useless to search for it. The most vigorous antiphlogistic treatment will be necessary to give the patient a chance of recovery.

Secondary hæmorrhage not unfrequently ensues, when the parts around the track of the wound slough by ulceration of the larger vessels injured by the ball. The bleeding vessel must, if possible, in this case, as well as if it is observed at the first receipt of the injury, be at once cut down upon and tied both above and below the opening. In the same way, portions of various organs may slough from the injuries received, and, by giving issue to their contents, may produce rapidly fatal symptoms.

In cases where the skin is not injured, but the parts beneath greatly bruised, it is recommended to make one or more incisions in order to clear out some of the coagulated blood, &c., and to permit the discharge of the slough. Where the bones and vessels are considerably broken, as sometimes happens in these cases, amputation is at once necessary. In all cases when the sloughs have separated the wound commences to granulate, and from this time, whether its progress be towards recovery or death, its treatment need not differ from that of wounds in a similar condition from common causes.

GUNNER, NAVAL, the highest rank in the grade of warrant officers in H.M. navy. A class of naval officers of whose multifarious duties very little is generally known, and a detailed account of which would excite surprise. It is sufficient herein to remark, that a naval gunner must of necessity be a man of considerable intelligence, as the benefits of all the evolutions necessary in the presence of an enemy would be neutralised, if he be deficient in skill, self-command, and decision. The following are some of his acquirements, duties, and responsibilities: he must, in the first place, have received a good ordinary education to enable him to pass the rigid examination expected of him. Not only is a regular course of instruction undergone on board the "Excellent" gunnery training ship, at Portsmouth, but on returning from foreign stations, and before being permitted to enter upon another ship, he is to present himself at the "Excellent," and be made proficient in any improvements in gunnery which may have been introduced during his absence. The discipline of a ship is much dependent on his judgment, forbearance and tact, and the contentment of the crew is seriously influenced more or less by the manner in which he conducts his duties, for he is the drill-master of the ship (subject in very large ships to the inspection of a gunnery-lieutenant). Assisted by his one to four or five mates, he has to instruct from 50 to 1000 men (according to the size of the ship), including the junior officers, usually styled "young gentlemen," in the great gun exercise, also with rifles, swords, pikes, and pistols; has charge of all the extensive and costly armaments and military stores, such as guns, small arms, powder, shot, shells, rockets, &c.; he is responsible for the various batteries, and that their requisites are kept at hand in convenient places, and in serviceable condition, ready for action at a moment's notice. A gunner, moreover, has charge of the magazine, and is required to be capable of working it in *total darkness;* and to be able to send up in the heat and excitement of action proper charges for certain guns, &c. He must be ready at calculation, at taking angles for ascertaining the distances of objects, and cutting his fuses accordingly with the nicest accuracy. He must have a considerable knowledge of practical geometry, to enable him to readily lay off lines for concentrating his fire, &c. He must have correct notions of laboratory work in the manufacture of the various compounds for fuses, blue lights, &c. He must keep particular accounts of his service expenditure of stores, only receiving his pay when these are approved by his commanding officers. In small vessels he keeps (with other warrant officers) a lieutenant's watch on deck, and therefore must be a thoroughly practical seaman, able to tack ship, rig and work a ship in general, for which he must have passed a severe examination by naval officers. He has constant charge of the main yard and main rigging of his ship, and also the fitting of boats for armed service. His sea-pay varies (according as he is a first, second, or third class gunner) from 120*l.* to 86*l.* per annum. He is obliged to dress (in uniform) with respectability and neatness for the sake of example. If married, the impossibility of saving money from his pay, renders his position one of some dissatisfaction in the service, and especially as the warrant officer is the only rank in the navy, from the admiral to the second class boy, which does not receive the same pay in harbour service as at sea, although his duties there are very often more harassing, and with more risk from boating, &c.; his harbour pay being, instead of 120*l.* reduced to 101*l.*, and 86*l.* reduced to 63*l.* per annum. He cannot leave the service until *entirely worn out in it,* without forfeiting all his servitude; and when pronounced by a medical survey to be unfit for further work, he can expect only a retirement of about 45*l.* per year upon the average; while if he die on service, not in action, nor suffering a violent death on active duty, there was during thirty years no provision for his widow. The widow's pension was withdrawn in 1830. The effect has, however, operated injuriously to the naval service of the country, as the emolument of gunners is considered to be so disproportionate to their responsibilities, as to have kept many good men from seeking the warrant. This is now happily under consideration; already has the Admiralty not only restored to warrant officers their rank as next to second masters, of which they were deprived in 1844; but in February, 1860, the pension to the widows of warrant officers was very considerately restored also. [BOATSWAIN.] The chief gunner's mate is a chief petty officer, and all the mates pass examination in the "Excellent."

GUNNERY is that branch of the art of war which comprehends the theory of military projectiles, and the manner of employing ordnance in the attack and defence of fortresses or positions.

Under the head of ARTILLERY will be found an account of the introduction of gunpowder for the purpose of discharging ball from cannon, and a description of the earlier forms in which they were made. Under the head of ORDNANCE is described the present construction of cannon and their weights and sizes. Representations of the forms of many ancient pieces of ordnance may be seen in the 'Treatise on Artillery,' by Diego Ufano, 1614, as well as in the 'Prattica Manuale di Artiglieria,' by Luigi Colliado, 1606. Generally the ancient fire-arms were so constructed as to discharge masses of enormous weight; and it is said, that when Mohammed II. besieged Constantinople, he employed pieces whose calibre (diameter of bore) was equal to 12 palms, and which projected against the walls of the city stones weighing 1200 lbs. At present a rapid succession of discharges from a comparatively small kind of ordnance is considered more efficacious, when directed against the walls of a fortress, than the few shots which can be fired from such unwieldy machines. The 13-inch shell which is now employed weighs, when loaded, about 200 lbs.; but when the French besieged the citadel of Antwerp in 1832, the Belgians brought up a mortar whose calibre was 24 inches, and whose shell when loaded weighed 1015 lbs. The effect produced by it was not, however, so great as had been anticipated.

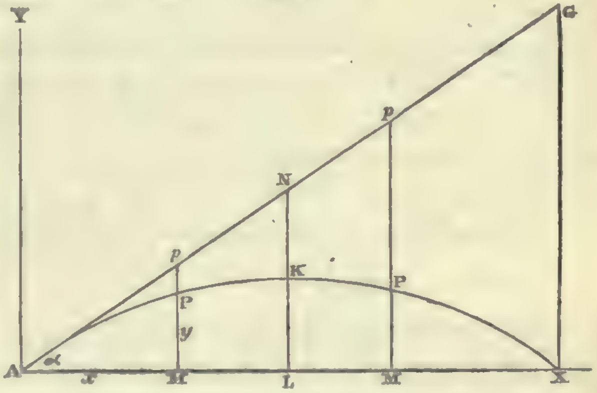
Tartalea appears to have been the first mathematician who wrote on the motion of balls when projected from fire-arms, and in his 'Quesiti et Inventione Diversi,' which was printed at Venice in 1546, he investigates a few particulars concerning that kind of motion; but the low state of the theory of such motions at that time may be imagined, when we consider that he thought it necessary to disprove the opinion, which then prevailed, that one part of the trajectory, or path, of a cannon-ball was rectilinear.

In 1638 Galileo published the 'Dialoghi delle Scienze Nuove,' in which, together with his investigations concerning the composition of motions in general, he shows that a shot projected from a gun describes a parabolic curve. He states that the shot is urged by the impulsive force of the powder in a rectilinear direction, coinciding with the axis of the bore, and that it would move with a uniform velocity if it were not continually deflected by the attraction of gravity from that direction; he shows also that this deflecting force, exerted in lines perpendicular to the horizon, would cause the shot to descend in such lines with a variable velocity. Now, the spaces which would be described in consequence of the projectile force, being proportional to the times of describing them,—and the spaces described in consequence of the earth's attraction being proportional to the squares of the times,—it followed, from the relation between the spaces so described, that the shot, which, according to the laws of the composition of motions, would always be at the intersection of the lines representing the spaces, must describe a curve with respect to which the corresponding lines would have the same relation; that is, a parabola.

Galileo expressly says that this curve would be described by the shot, if it were not resisted by the air; he was aware of that resistance, and he proposes a method of finding its effects. It is now well known that the resistance of the air, when the motion of the projectile is rapid, is such as to cause the latter to describe a curve-line very different from a parabola; and, consequently, that the parabolic theory, as it is called, is of small importance as a guide to the practical artillerist; yet, as it possesses a certain interest on account of its connection with the general subject of projectiles, and is a step to the investigation of the real trajectory, we will proceed, before entering upon that investigation, to give a demonstration of the fundamental proposition, and exhibit a few of the principal deductions which are usually made from it.

The following investigation of the curve described by the centre of gravity of a shot projected obliquely in a vacuum is extracted from Captain Boxer's 'Treatise on Artillery:'—

Fig. 1.



Let V = the initial velocity in the direction AG.

α = the angle GAX made by the direction of projection with horizontal plane.

x and y = the horizontal and vertical co-ordinates at any point P in the curve, from the point of departure A as the origin.

t = the time of flight to the point P.

AX = the whole horizontal range.

LK = the greatest height of ascent.

T = the time of flight to the point X.

Now, if no force were acting on the projectile it would, by the first law of motion, move on for ever in the line AG with the velocity V. This motion is, however, in fact modified by the action of two forces—the resistance of the atmosphere and gravity; and as it is proposed to leave the former out of consideration for the present, it only remains to compound the motion produced by gravity, which, by the second law of motion, is the same as it would produce upon a body at rest, with the uniform motion in the line AG, in order to obtain the actual motion of the shot upon the hypothesis assumed.

We have then Ap = distance described with the velocity V in the time = t = Vt.

$$x = AM = Ap \cos pAM = Vt \cos \alpha, \qquad (1)$$

$$Mp = Ap \sin pAM = Vt \sin \alpha,$$

pP = distance described from rest by the action of gravity during the time $t = \frac{1}{2} g t^2$,

$$y = MP = Mp - pP = Vt \sin \alpha - \frac{1}{2} gt \qquad (2)$$

and substituting in (2) the value of t derived from (1),

$$y=\frac{V\sin\alpha\,.\,x}{V\cos\alpha}-\tfrac{1}{2}g\frac{x^2}{V^2\cos^2\alpha}=x\tan\alpha-\frac{gx^2}{2V^2\cos^2\alpha}\qquad(3)$$

Let h represent the height which a body must fall to obtain the velocity (V), when acted upon by the force of gravity only; then

$$V^2=2gh,$$

and substituting this value in equation (3)

$$y=x\tan\alpha-\frac{x^2}{4h\cos^2\alpha}\qquad(4)$$

which is the equation to the parabola, the diameters of the curve being parallel to AY. From this equation all the properties relating to projectiles moving in a vacuum may be derived.

To find the Time of Flight.—To find the time of flight T we have

$$GX=AG\sin\alpha=VT\sin\alpha$$
$$GX=\tfrac{1}{2}gT^2$$
$$\therefore\tfrac{1}{2}gT^2=VT\sin\alpha\text{— }\therefore\text{ and }\quad T=\frac{2V\sin\alpha}{g}.\qquad(5)$$

The time of flight varies, therefore, with the sine of the angle of elevation.

The same result might also have been obtained by putting $y=o$ in equation (2).

To find the Horizontal Range.—To find the horizontal range we have,

$$AX=AG\cos\alpha$$
$$AG=VT$$
$$T=\frac{2V\sin\alpha}{g}\qquad\text{by (5)}$$
$$\therefore AX=\frac{2V^2\sin\alpha\cos\alpha}{g}$$
$$\text{or, }AX=2h\sin2\alpha,\qquad(6)$$

The same result would be obtained by putting $y=o$ in equation (3).

It appears, then, that when h, or the initial velocity, is constant, AX, or the horizontal range, varies as sine 2α; and the value of AX is greatest when $2\alpha=90$, or $\alpha=45$, in which case $AX=2h$.

Again, with the same initial velocity there are generally two angles which will give the same horizontal range. For the sine $2\alpha=\sin(108^\circ-2\alpha)$ and the ranges will be equal at equal distances from 45°.

Lastly, with the same angle of projection the initial velocities are as the square root of the ranges.

To find the greatest Height to which the Shot will Rise.—In order to find the greatest height to which the shot will rise, bisect AX in L, then $AL=L\sin2\alpha=2h\sin\alpha\cos\alpha$; and putting $ML=z$, $X=AM=2h\sin\alpha\cos\alpha\pm z$, substituting this value (3),

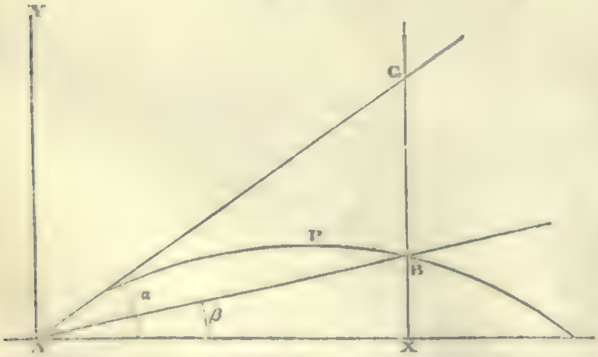
$$MP=y=(2h\sin\alpha\cos\alpha\pm z)\tan\alpha-\frac{(2h\sin\alpha\cos\alpha\pm z)^2}{4h\cos^2\alpha}$$
$$=2h\sin^2\alpha\pm z\tan\alpha-\left\{h\sin^2\alpha\pm2\tan\alpha+\frac{z^2}{4h\cos^2\alpha}\right\}$$
$$=h\sin^2\alpha-\frac{z^2}{4h\cos^2\alpha}\qquad(7)$$

MP or y has, therefore, its greatest possible value when $z=o$.

LK is therefore this greatest height, and is equal to $h\sin^2\alpha$. Equation (7) shows that the curve is symmetrical with respect to the line LK.

To find the Time of Flight, Range, &c., when the Plane is not Horizontal.—Should the line joining the object and the piece not lie in a horizontal plane, then, as the direction of the force of gravity is not perpendicular to the plane in which the gun and object are situated, the foregoing formulæ will not be applicable.

Figure 2.



Let AX represent a section of the horizontal plane, and AB that of the plane containing the gun and object B,

$$\angle GAX=\alpha$$
$$\angle BAX=\beta$$
$$T=\text{time of describing the curve }APB.$$

$$GB:AG::\sin GAB:\sin ABG$$
$$\angle GAB=(\alpha-\beta);$$
$$\angle ABG=180-\angle ABX;$$
$$\sin ABG=\sin\angle ABX=\cos\beta;$$
$$GB=\tfrac{1}{2}gT^2;\ AG=VT.$$

By substituting these values in the above proportion we have

$$\tfrac{1}{2}gT^2:VT::\sin(\alpha-\beta):\cos\beta$$
$$\tfrac{1}{2}gT^2\cos\beta=VT\sin(\alpha-\beta)$$
$$T=\frac{2V\sin(\alpha-\beta)}{g\cos\beta}\qquad(1)$$

Substituting this value of T in the equator $AG=VT$,

$$AG=\frac{2\sin(\alpha-\beta)\,v^2}{g\cos\beta}$$
$$=4h\frac{\sin(\alpha-\beta)}{\cos\beta}$$

$$\text{Also, }\sin AGB=\cos GAX=\cos\alpha$$
$$\sin ABG=\sin ABX=\cos\beta.$$

Substituting these values in the proportion

$$AB:AG::\sin AGB:\sin ABG$$

we have,

$$AB:4h\frac{\sin(\alpha-\beta)}{\cos\beta}::\cos\alpha:\cos\beta$$
$$::AB=4h\frac{\sin(\alpha-\beta).\cos\alpha}{\cos^2\beta}\qquad(2)^*$$

If the plane be a descending one, the angle β must be considered *negative.*

On the Application of the Equation to the Curve described by a Body in a Vacuum to Mortar Practice.—Although the foregoing theory will give results very different from those found in practice with shot projected with great velocities, still, for the ordinary practice with mortars, it will not be far from correct, as may be seen by an inspection of the following tables, extracted from a work entitled 'Traité de Blastique,' by M. Didion; the mortars corresponded to our 8-inch and 10-inch.

Table of Ranges calculated without taking into account the resistance of the air, and the experimental ranges:

RANGES OF SHELLS 38 CENTIMÈTRES DIAMETER.				RANGES OF SHELLS 28 CENTIMÈTRES DIAMETER.			
45° Elevation observed.	Elevation 30°.			45° Elevation observed.	Elevation 30°.		
	Observed.	Calculated.	Difference.		Observed.	Calculated.	Difference.
Mèt.	Mètres.	Mètres.	Mètres.	Mèt.	Mètres.	Mètres.	Mètres.
457	383	396	+13	343	290	298	+ 8
734	637	637	0	629	561	545	− 16
1132	980	982	+ 2	1146	1011	993	− 13
1555	1355	1350	− 5	1792	1690	1552	− 138
1757	1516	1522	+ 6				

---

[*] Equations (1) and (2) may also be determined from the equations to the curve in the following manner:—

$$AB\cos\beta=x=V\cos\alpha T$$
$$AB\sin\beta=y=V\sin\alpha T-\tfrac{1}{2}gT^2$$
$$\tan\beta=\frac{y}{x}=\tan\alpha-\frac{g}{2V\cos\alpha}T$$
$$\therefore T=\frac{2V(\tan\alpha-\tan\beta)\cos\alpha}{g}\qquad(1)$$
$$=\frac{2V\sin(\alpha-\beta)}{g\cos\beta}$$

Again,

$$y=x\tan\alpha-\frac{gx^2}{2V^2\cos^2\alpha}$$
$$R\sin\beta=R\cos\beta\tan\alpha-\frac{gR^2\cos^2\beta}{2V^2\cos^2\alpha}$$
$$\frac{gR\cos^2\beta}{2V^2\cos^2\alpha}=\cos\beta\tan\alpha-\sin\beta$$
$$=\frac{\sin(\alpha-\beta)}{\cos\alpha}$$
$$R=\frac{2V^2\sin(\alpha-\beta)\cos\alpha}{g\cos^2\beta}$$
$$=\frac{4h\sin(\alpha-\beta)\cos\alpha}{\cos^2\beta}\qquad(2)$$

It appears from the latter table that up to about 1400 yards the ranges with different degrees of elevation might be calculated by the parabolic theory from the ranges for 45°, the initial velocities in the above tables having been computed from the formula

$$2\,h = \text{range with an elevation of } 45°,$$

the times of flight from the formula

$$T = \frac{\text{Range}}{V \cos a} = \frac{\text{Range}}{\sqrt{2\,gh}\,.\,\cos a}.$$

The theory of the motions of projectiles would therefore be very simple if we might neglect the effects produced by the resistance of the air during the flight of the shot; but, in fact, when high charges of powder are employed, the trajectory bears no resemblance to a parabolic curve, and can only be expressed by equations of a transcendental nature.

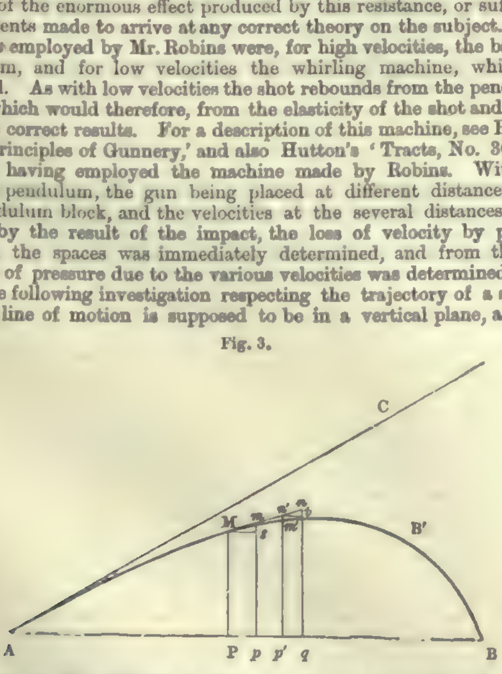
From the time of Galileo to that of Newton, though the subject of the movement of projectiles occupied the attention of nearly every mathematician in Europe, it seems to have been taken for granted that the resistance of the air was too small to deserve much consideration. Even Dr. Halley, while he admitted that its effects might become sensible when the projectile was light, conceived that it would be of no importance when the heavier kinds of shot were employed; and it is easy to conceive that the ideas then entertained of the form of the trajectory were very wide of the truth. Huygens himself, from an unfounded opinion that the resistance was proportional to the velocity simply, asserted that the path of a shot through the air was a logarithmic curve.

It was reserved for Newton to develop the true laws of the resistance experienced by bodies moving in fluid media, and to make a near approach to the form of the curve described by a projectile in the air. In a scholium to prop. 4 ('Principia,' lib. ii.), he shows that such resistance is proportional to the square of the velocity; and elsewhere he proves that, *cæteris paribus*, the resistance to globular bodies varies as the squares of their diameters and as the density of the medium. He also takes notice of the retardation which would be caused by the condensation of the fluid in front of the body when the motion is rapid, and of that produced in consequence of the air not being able to fill up immediately the partial vacuum which exists behind the ball during its flight. And, in a scholium to prop. 10, he explains that the curve described in a uniformly resisting medium is a species of hyperbola having the asymptote of the descending branch in a vertical position.

The evidence afforded by the investigations and experiments of Newton, concerning the effects produced by the resistance of the air, induced a few mathematicians to adopt in their researches the principles which he had established. Daniel Bernoulli appears to have been the first who did so; but, from an example in which he compares the ascent of a cannon-ball in the air when projected vertically upwards, with the height to which it would rise in vacuo with the same initial velocity, he has manifestly estimated the resistance much too low. And it was not till 1746, when Mr. Robins submitted a paper on the resistance of the atmosphere to the Royal Society, that any correct idea was formed of the enormous effect produced by this resistance, or sufficient experiments made to arrive at any correct theory on the subject. The methods employed by Mr. Robins were, for high velocities, the ballistic pendulum, and for low velocities the whirling machine, which he invented. As with low velocities the shot rebounds from the pendulum block, which would therefore, from the elasticity of the shot and block, not give correct results. For a description of this machine, see Robins' 'New Principles of Gunnery,' and also Hutton's 'Tracts, No. 36,' Dr. Hutton having employed the machine made by Robins. With the ballistic pendulum, the gun being placed at different distances from the pendulum block, and the velocities at the several distances determined by the result of the impact, the loss of velocity by passing through the spaces was immediately determined, and from this the amount of pressure due to the various velocities was determined.

In the following investigation respecting the trajectory of a shot in air, the line of motion is supposed to be in a vertical plane, and the resistance of the medium is supposed to vary proportionally to the square of the velocity at every point of the curve.

Fig. 3.



Let A B′ B *fig.* 3, be the curve, of which let M *m* be an indefinitely small arc described in the unit of time (as one second) in consequence of the projectile force; then, if the force of gravity and the resistance of the air were not to act on the shot, the latter might in the next equal portion of time be supposed to describe the line *m n* in the direction of a tangent to the curve at M. But, during this portion of time, let the diminution of motion caused by the resistance of the air be represented by *n n′* and the deflection produced by gravity be represented by *n′ m′*; then *m′* will be the place of the shot at the end of that portion of time. Draw the vertical lines M P, *m p*, *n′ p′*, *n q*; and the horizontal lines M *s*, *n′t*. Let A P $= x$, P M $= y$, and the arc A M $= z$; let also R represent the force of the air's resistance and g the force of gravity (both forces being measured by the velocities which they would produce, at the end of one second, in a body moving by their impulses).

Then, by the laws of motion, the velocities varying proportionally to the forces and times of motion, we have $R\,dt$ and $g\,dt$ for the resistance nn' and the force of descent nt during the evanescent portion of time expressed by dt. And by the resolution of motions $\frac{nt}{n'n}\,R\,dt$ will express the diminution of velocity vertically in consequence of the resistance, while $\frac{n't}{n'n}\,R\,dt$ will express the horizontal diminution on the same account. But from the similar triangles M*sm*, *n′tn*, we have

$n'n : n't :: Mm : ms :: dz : dy$; whence $\frac{nt}{n'n} = \frac{dy}{dz}$.

Also $n'n : n't :: Mm : Ms :: dz : dx$; whence $\frac{n't}{n'n} = \frac{dx}{dz}$.

Therefore the vertical diminution becomes $\frac{R\,dy\,dt}{dz}$; and the diminution horizontally, $\frac{R\,dx\,dt}{dz}$. To the former adding gdt for the action of gravity, as above, we have, for the whole vertical diminution of velocity, $\frac{R\,dy\,dt}{dz} + gdt$.

Now the vertical and horizontal velocities of the shot in vacuo, at M, being represented by *ms* and M*s*; that is, by $\frac{dy}{dt}$ and $\frac{dx}{dt}$ respectively: and, in the ascending branch of the trajectory the forces arising both from gravity and the resistance of the air being retardative, the velocities in the next second of time will be; in the horizontal direction $\frac{dx}{dt} - d\left(\frac{dx}{dt}\right)$, and in the vertical direction, $\frac{dy}{dt} - d\left(\frac{dy}{dt}\right)$: that is, the diminutions of velocity are, in the former direction, $-\,d\left(\frac{dx}{dt}\right)$ and, in the latter, $-\,d\left(\frac{dy}{dt}\right)$. Consequently,

$$\frac{R\,dx\,dt}{dz} = -\,d\left(\frac{dx}{dt}\right) \;.\;.\;.\;.\;.\; \text{(I)},$$

$$\text{and } \frac{R\,dy\,dt}{dz} + gdt = -\,d\left(\frac{dy}{dt}\right) \;.\;.\;.\;.\;.\; \text{(II)}.$$

But the resistance experienced by a shot moving through the air is, agreeably to the laws of hydrodynamics, represented by some part of the weight of a column of the fluid, whose base is a section through the shot perpendicular to the line of its motion, and whose height is that space through which a body would descend in vacuo to acquire the actual velocity of the shot. Therefore let A be the area of such section, v the velocity of the shot, and h the height due to that velocity; and let D be the density of the air; then $h = \frac{v^2}{2g}$ and $\frac{v^2}{2g}\,A\,.\,D =$ the weight of the column. Putting $2gp$ to represent some number which is to be determined by experiment we shall have $pv^2\,A\,.\,D$ for the resistance, or for the motion destroyed in one second, and $pv^2\,A\,.\,D\,dt$ for the motion destroyed in the time dt. But, by dynamics, $\frac{\text{momentum}}{\text{mass}} =$ velocity; therefore, if M represent the mass of the shot, $\frac{pv^2\,A\,.\,D\,dt}{M}$ is the velocity destroyed by the resistance in the time dt; and this is what is expressed above by $R\,dt$: consequently we have $R = \frac{pv^2\,A\,.\,D}{M}$; or, representing $\frac{pA\,.\,D}{M}$ by $\frac{1}{H}$, and for v putting its value $\frac{dz}{dt}$ we have $R = \frac{1}{H}\frac{dz^2}{dt^2}$. Then the general equations (I) and (II) will become

$\frac{dx\,dz}{H\,dt'} = -\,d\left(\frac{dx}{dt}\right)$ and $\frac{dy\,dz}{H\,dt} + gdt = -\,d\left(\frac{dy}{dt}\right)$; but dt being considered as constant, they may be put in the form

$$\frac{dx\,dz}{H} = -\,d^2x, \text{ and } \frac{dy\,dz}{H} + gdt^2 = -\,d^2y.$$

From the first of these equations we have $dz = -\frac{\mathrm{H}\, d^2x}{dx}$; which, being substituted in the latter, gives

$\frac{dy\, d^2z}{dx} + g dt^2 = -d^2y$; or, after reduction, $dt^2 = -d\left(\frac{dy}{dx}\right)\frac{dx}{g}$.

But, multiplying the above equation for $-d^2x$ by $\mathrm{H}\, dt^2$, it becomes $dx\, dz\, dt^2 = -\mathrm{H}\, dt^2 d^2x$; which, on substituting in the first member the preceding value of dt^2, becomes

$$dz\, d\left(\frac{dy}{dx}\right) dx^2 = \mathrm{H}\, g\, dt^2\, d^2x.$$

Again $dz = \sqrt{(dx^2 + dy^2)} = dx\sqrt{\left(1 + \frac{dy^2}{dx^2}\right)}$; therefore the last equation may be put in the form

$$dx^2\, d\left(\frac{dy}{dx}\right)\sqrt{\left(1 + \frac{dy^2}{dx^2}\right)} = \mathrm{H}\, g\, dt^2\, d^2x,$$

$$\text{or } d\left(\frac{dy}{dx}\right)\sqrt{\left(1 + \frac{dy}{dx}\right)} = \mathrm{H}\, g\, dt^2\, \frac{d^2x}{dx^3} \;.\;.\;.\;.\;.\; \text{(III)}.$$

This equation, being integrated, would determine the relation between x and y in the trajectory; and, since dt is constant, the integral of the second member is evidently, $-\frac{\mathrm{H}\, g dt^2}{2\, dx^2}$. To obtain that of the first member, let t represent the tangent of half the angle made by a horizontal line and a tangent to the curve at each point; then, by trigonometry, we shall have $\frac{dy}{dx}$ (=the tangent of the whole angle) $= \frac{2\,\mathrm{t}}{1-\mathrm{t}^2}$ and $d\left(\frac{d}{dx}\right) = \frac{2\,(1+\mathrm{t}^2)}{(1-\mathrm{t}^2)^2}\, d\,\mathrm{t}$; also $\sqrt{\left(1 + \frac{dy^2}{dx^2}\right)} = \frac{1+\mathrm{t}^2}{1-\mathrm{t}^2}$: consequently, that first member becomes $\frac{2\,(1+\mathrm{t}^2)^2\, dt}{(1-\mathrm{t}^2)^3}$, whose integral is $\frac{\mathrm{t}+\mathrm{t}^3}{(1-\mathrm{t}^2)^2} + \int\frac{d\,\mathrm{t}}{1-\mathrm{t}^2}$, or $\frac{\mathrm{t}+\mathrm{t}^3}{(1-\mathrm{t}^2)^2} + \frac{1}{2}\log.\frac{1+\mathrm{t}}{1-\mathrm{t}}$; therefore the integral of equation (III) is

$$\frac{\mathrm{t}+\mathrm{t}^3}{(1-\mathrm{t}^2)^2} + \frac{1}{2}\log.\frac{1+\mathrm{t}}{1+\mathrm{t}} = \mathrm{C} - \frac{\mathrm{H}\, g dt^2}{2\, dx^2} \;.\;.\;.\;.\;.\; \text{(IV)},$$

where C is an arbitrary constant.

Now, let E represent the angle of elevation at the point A, or the angle C A B; at this point we have $dx = dz \cos \mathrm{E}$, and $dx^2 = dz^2 \cos^2 \mathrm{E}$; also, at the same point, $ds = \mathrm{v}\, dt$, v being the initial velocity of the shot. Therefore

$dx^2 = \mathrm{v}^2\, dt^2 \cos^2 \mathrm{E}$, and $\frac{dt^2}{dx^2} = \frac{1}{\mathrm{v}^2 \cos^2 \mathrm{E}}$; but since, by dynamics, $\mathrm{v}^2 = 2g\mathrm{h}$, we have evidently,

$$\frac{dt^2}{2dx^2} = \frac{1}{4g\mathrm{h} \cos^2 \mathrm{E}};$$

then, if this value be substituted in (IV), and tan ½ E be put for t, that equation will become

$$\frac{\tan \frac{1}{2}\mathrm{E} + \tan^3 \frac{1}{2}\mathrm{E}}{(1+\tan^2 \frac{1}{2}\mathrm{E})^2} + \frac{1}{2}\log\frac{1+\tan \frac{1}{2}\mathrm{E}}{1-\tan \frac{1}{2}\mathrm{E}} = \mathrm{C} - \frac{\mathrm{H}}{2\mathrm{h}\cos^2 \mathrm{E}} \;.\;.\;.\;.\;.\; \text{(V)},$$

from whence the value of C might be found.

Substituting in the equation (IV) the above value of dt^2, viz. $-d\left(\frac{dy}{dx}\right)\frac{dx}{g}$, and putting for $\frac{dy}{dx}$ its value, $\frac{2\mathrm{t}}{1-\mathrm{t}^2}$, that equation becomes

$\frac{\mathrm{t}+\mathrm{t}^3}{(1-\mathrm{t}^2)^2} + \frac{1}{2}\log.\frac{1+\mathrm{t}}{1-\mathrm{t}} = \mathrm{C} + \frac{\mathrm{H}}{2dx}\, d\left(\frac{2\mathrm{t}}{1-\mathrm{t}^2}\right)$; whence we obtain

$$\frac{2dx}{\mathrm{H}} = -\frac{d\left(\frac{2\mathrm{t}}{1-\mathrm{t}^2}\right)}{\mathrm{C} - \frac{\mathrm{t}+\mathrm{t}^3}{(1-\mathrm{t}^2)^2} - \frac{1}{2}\log.\frac{1+\mathrm{t}}{1-\mathrm{t}}} \;.\;.\;.\;.\;.\; \text{(VI)}.$$

But, as this expression does not admit of being integrated by any known rules, mathematicians have endeavoured to obtain an approximate value of the integral; and Bezout, whose method has been adopted in the above investigation, employs the following process for that purpose. Developing the expression $\frac{1}{2}\log.\frac{1+\mathrm{t}}{1-\mathrm{t}}$ in an infinite series, putting that series in the form of a fraction, whose denominator is $(1-\mathrm{t}^2)^2$, and then substituting it in the preceding equation, the latter becomes, after reduction,

$$\frac{2dx}{\mathrm{H}} = \frac{-d\left(\frac{2\mathrm{t}}{1-\mathrm{t}^2}\right)}{\mathrm{C} - \frac{2\mathrm{t}}{1-\mathrm{t}^2}\left[1 + \frac{\frac{2}{3}\mathrm{t}^2 + \frac{4}{15}\mathrm{t}^4 + \&c.}{1-\mathrm{t}^2}\right]} \;.\;.\;.\;.\;.\; \text{(VII)}.$$

Assuming the last factor in the denominator to be constant, and representing it by b, we have

$$\frac{2dx}{\mathrm{H}} = \frac{-d\left(\frac{2\mathrm{t}}{1-\mathrm{t}^2}\right)}{\mathrm{c} - \frac{2\mathrm{t}}{1-\mathrm{t}^2}.\,\mathrm{b}} \;.\;.\;.\;.\;.\; \text{(VIII)}$$

which can easily be integrated, since the second member is equivalent to the differential of a logarithm; thus we have

$$\frac{2x}{\mathrm{H}} = \frac{1}{\mathrm{b}}\log.\left(\mathrm{c} - \frac{2\mathrm{bt}}{1-\mathrm{t}^2}\right) + \mathrm{c}' \;.\;.\;.\;.\;.\; \text{(IX)},$$

where C′ is a new arbitrary constant.

The value of b in equation (VII), when simplified, will be found to be equal to ½ sec. E + ½ cotan. E log. tan. (45° + ½ E); and Bezout has computed from this formula a table of its values for every degree of elevation. At 40° we have b = 1·1073 merely; therefore, at elevations not exceeding that number of degrees, we may, without much error, consider b as constant and equal to unity. The value of c, when obtained from equation (V) and simplified, is found to be equal to $\frac{\mathrm{H}}{4\mathrm{h}\cos \mathrm{E}} + \mathrm{b}\tan.\mathrm{E}$; and the value of C′ may be obtained by the following process.

At A, the point of projection, we have $x = 0$, and $\frac{2\mathrm{t}}{1-\mathrm{t}^2} = \tan.\mathrm{E}$; therefore, at that point, the equation (IX) becomes

$$\frac{2x}{\mathrm{H}} = \frac{1}{\mathrm{b}}\log.(\mathrm{C} - \mathrm{b}\tan.\mathrm{E}) + \mathrm{C}';$$

whence

$$\mathrm{C}' = -\frac{1}{\mathrm{b}}\log.(\mathrm{C} - \mathrm{b}\tan.\mathrm{E}), \text{ or } = -\frac{1}{\mathrm{b}}\log.\frac{\mathrm{H}}{4\mathrm{h}\cos^2 \mathrm{E}}$$

$$\text{Therefore } \frac{2x}{\mathrm{H}} = \frac{1}{\mathrm{b}}\log.\frac{4\mathrm{h}\cos^2 \mathrm{E}}{\mathrm{H}}\left(\mathrm{C} - \frac{2\mathrm{bt}}{1-\mathrm{t}^2}\right);$$

and putting e for the base of the hyperbolic logarithms (= 2·71828), we have

$$e^{\frac{2\mathrm{b}x}{\mathrm{H}}} = \frac{4\mathrm{h}\cos^2 \mathrm{E}}{\mathrm{H}}\left(\mathrm{C} - \frac{2\mathrm{bt}}{1-\mathrm{t}^2}\right) \;.\;.\;.\;.\;.\; \text{(X)},$$

$$\text{and } \frac{2\mathrm{t}}{1-\mathrm{t}^2} = \frac{1}{\mathrm{b}}\left[\mathrm{C} - \frac{\mathrm{H}}{4\mathrm{h}\cos^2 \mathrm{E}}.\, e^{\frac{2\mathrm{b}x}{\mathrm{H}}}\right].$$

But $\frac{dy}{dx} = \frac{2\mathrm{t}}{1-\mathrm{t}^2}$; therefore,

$$dy = \frac{\mathrm{C}\, dx}{\mathrm{b}} - \frac{\mathrm{H}\, dx}{4\mathrm{bh}\cos^2 \mathrm{E}}\, e^{\frac{2\mathrm{b}x}{\mathrm{H}}}.$$

This equation being integrated, and the constant determined on the supposition that $y = 0$ when $x = 0$, we have

$y = \frac{\mathrm{C}x}{\mathrm{b}} + \frac{\mathrm{H}^2}{8\mathrm{b}^2\mathrm{h}\cos^2 \mathrm{E}}\left(1 - e^{\frac{2\mathrm{b}x}{\mathrm{H}}}\right)$; or putting for C its value,

$$y = \left[\tan.\mathrm{E} + \frac{\mathrm{H}}{4\mathrm{b}^2\mathrm{h}\cos^2 \mathrm{E}}\right]x + \frac{\mathrm{H}^2}{8\mathrm{b}^2\mathrm{h}\cos^2 \mathrm{E}}\left(1 - e^{\frac{2\mathrm{b}x}{\mathrm{H}}}\right) \;.\;.\; \text{(XI)}.$$

By substituting in this equation any assumed values of x, we should obtain the corresponding vertical ordinates; and thus the form of the trajectory would be determined, approximatively. But, if the objec is merely to obtain the horizontal range, make $y = 0$ in the equation; then the latter will, after reduction, become

$$\frac{2\mathrm{b}}{\mathrm{H}}\, x\log.e = \log.\left[1 + \frac{2\mathrm{b}}{\mathrm{H}}\left(\frac{2\mathrm{bh}}{\mathrm{H}}\sin 2\mathrm{E} + 1\right)x\right].$$

Substituting in this equation different numbers for x, that which renders the two members equal to each other will express the required extent of the range.

In the preceding investigation, g has been taken to represent the accelerative force of gravity, or that by which the shot would descend in vacuo; but, in fact, it should represent the accelerative force by which the shot descends in air. And, in order to obtain the latter force, let r represent the semi-diameter of the shot, π the ratio of the circumference of a circle to its diameter (= 3·14159), D the density of the air, and D′ that of the shot. Then $\frac{4}{3}\pi r^3 \mathrm{D}'$ will express the weight of the shot in vacuo, and $\frac{4}{3}\pi r^3 \mathrm{D}$ the weight of an equal volume of air; therefore, $\frac{4}{3}\pi r^3 (\mathrm{D}' - \mathrm{D})$ is the weight of the shot in air, and $\frac{4}{3}\pi r^3 g\, (\mathrm{D}' - \mathrm{D})$ is the motive power by which the shot descends; the latter, being divided by the weight of the shot, expressed as above, gives $g\,\frac{\mathrm{D}' - \mathrm{D}}{\mathrm{D}'}$ for the accelerative power required. But if the shot be of lead or iron, whose weight far exceeds that of an equal volume of air, the term D may be considered as equal to zero, and the accelerative power may be represented by g, the force of gravity on a body in vacuo.

By differentiating the equation (XI), making $dy=o$, and, from the resulting equation, obtaining the value of x; then, on substituting this value in equation (XI), the resulting value of y would be that of the greatest vertical ordinate of the curve, while the said value of x is the corresponding abscissa.

What is called the point blank range is the distance from a point on the ground, vertically under the chamber of the gun or howitzer, to the point at which the shot strikes the ground after the discharge, the axis of the bore being supposed to be in a horizontal position, or parallel to the ground if the latter should be inclined to the horizon. The extent of such range may be determined from the equation (XI), by making $\mathrm{E}=o$ and considering y as negative. In this case the said equation becomes, b being equal to unity,

$$-y = \frac{\mathrm{H}x}{4\mathrm{h}} + \frac{\mathrm{H}^2}{8\mathrm{h}}\left(1-e^{\frac{2x}{\mathrm{H}}}\right);$$

where y is the height of the gun above the level of the spot on which the shot falls. And the equation, after reduction, becomes

$$\frac{2x}{\mathrm{H}}\ \log.\ e = \log.\frac{2\,\mathrm{H}x+\mathrm{H}^2+8\,\mathrm{h}y}{\mathrm{H}^2};$$

in which, substituting for x different assumed values, that which renders the two members equal to each other will be the required range.

The *but en blanc* of the French is frequently called the line of metal range, and signifies the distance from the chamber of the gun to the point where the trajectory of the shot crosses (the second time) a line joining the tops of the base, and muzzle rings, and produced. Here the axis of the gun, which is always a tangent to the trajectory at the nearest extremity, makes a small angle with the said line, depending on the dispart, or the difference between the semi-diameters of the gun at the base and muzzle.

Now, to find the time of flight: from the equation (IV); by reducing the logarithm to a series and proceeding as before, we shall have

$$\mathrm{H}g\ dt^2=2\,dx^2\left(c-\frac{2\mathrm{b}t}{1-t^2}\right);$$

and having found, from the equation (X), that $c-\frac{2\mathrm{b}t}{1-t^2}$ is equal to $\frac{\mathrm{H}}{4\mathrm{h}\cos^2\mathrm{E}}e^{\frac{2\mathrm{b}x}{\mathrm{H}}}$; we get

$$\mathrm{H}g\ dt^2=\frac{\mathrm{H}\ dx^2}{2\mathrm{h}\cos^2\mathrm{E}}e^{\frac{2\mathrm{b}x}{\mathrm{H}}};\ \text{or}\ dt=\frac{dx\ e^{\frac{\mathrm{b}x}{\mathrm{H}}}}{\cos\mathrm{E}\ \sqrt{2g\mathrm{h}}};$$

which being integrated gives $t=e^{\frac{\mathrm{b}x}{\mathrm{H}}}\cdot\frac{\mathrm{H}}{\mathrm{b}\cos\mathrm{E}\ \sqrt{2g\mathrm{h}}}+\mathrm{C}$, where C is an arbitrary constant.

Now, to obtain C; since t (the time of flight) $=o$ when $x=o$, by substituting those values in the equation, the latter becomes

$$o=\frac{\mathrm{H}}{\mathrm{b}\cos\mathrm{E}\ \sqrt{2g\mathrm{h}}}+\mathrm{C};\ \text{whence}\ \mathrm{C}=-\frac{\mathrm{H}}{\mathrm{b}\cos\mathrm{E}\ \sqrt{2g\mathrm{h}}}$$

and consequently $t=\frac{\mathrm{H}}{\mathrm{b}\cos\mathrm{E}\ \sqrt{2g\mathrm{h}}}\left(e^{\frac{\mathrm{b}x}{\mathrm{H}}}-1\right)$.

From which equation, on substituting the value of x (the horizontal range), which is supposed to be given, the time t of the flight of the projectile will be obtained.

It may be observed here that a knowledge of the time during which a shell will describe its trajectory is of great importance, since it enables the gunner so to regulate the length of the fuse, that the shell may explode nearly at the moment that it has reached the object which it is intended to destroy.

Note.—In determing the trajectory, the range, and the time of flight, by the above formulæ, the operations must be performed by the aid of logarithms.

It is of the first importance, in obtaining from the above formulæ a near approximation to the required values, that a correct measure of the velocity with which a shot issues from the mouth of a gun should be obtained; and the determination of such velocity, when the charge of powder is given, is the object of the following investigation, which, using the differential notation, is taken from the third volume of Dr. Hutton's Tracts.

Let r = the semi-diameter of the shot, or of the bore.
D' = the specific gravity of the shot.
$\pi = 3{\cdot}1416$ (the ratio of the circumference of a circle to its diameter).
$g = 32\frac{1}{6}$ feet.
$m = 33120$ oz. (the pressure of the atmosphere on 1 square foot).
w = the weight of the shot.
a = the distance from the bottom of the chamber to the hinder part of the ball.
b = the length of the bore.
n = the ratio of the expansive force of fired gunpowder to the pressure of the atmosphere.
v = the velocity of the shot on leaving the gun.
x = any variable distance of the shot, in the barrel, from the bottom of the chamber.
Then $r^2\pi$ = the area of a transverse section through the bore, or of a section through the shot; and
$nmr^2\pi$ = the force of the powder on the hinder part of the ball.

But the expansive force of powder being supposed to be inversely proportional to its density, or to the space which it occupies in the barrel, we have
$\frac{1}{a}:\frac{1}{x}::mnr^2\pi:\frac{mnar^2\pi}{x}$ (= the motive force of the powder at any point, in the barrel, whose distance from the bottom of the chamber $=x$).

Consequently, dividing this term by the weight of the shot, we have $\frac{mnar^2\pi}{wx}$ for the accelerative force of the powder on the shot at that point; from this term subtracting $\frac{mr^2\pi}{w}$, which expresses the retardation arising from the pressure of the atmosphere against the front of the ball while moving in the barrel, the accelerative force becomes $\frac{mr^2\pi}{w}\left(\frac{na}{x}-1\right)$; let this be represented by f. Now, by the theory of forces, we have
$vdv\ [=gfdx]=\frac{gmr^2\pi}{w}\left(\frac{nadx}{x}-dx\right)$; and the integral of this equation is

$$\tfrac{1}{2}v^2=\frac{gmr^2\pi}{w}\ (na\ \text{hyp. log.}\ x-x)+\mathrm{C};$$

where C is an arbitrary constant.

To find this constant; since $v=o$ when $x=a$, on substituting these values the equation becomes

$$o=\frac{gmr^2\pi}{w}\ (na\ \text{hyp. log.}\ a-a)+\mathrm{C};$$

from which C being found and substituted in the preceding equation, the complete integral becomes after reduction, and substituting b for x,

$$v=\sqrt{\left[\frac{2gmr^2\pi}{w}\left(na\ \text{hyp. log.}\ \frac{b}{a}+a-b\right)\right]}:$$

or substituting for w its value, namely, $\frac{4}{3}r^3\pi\,\mathrm{D}'$, we obtain for the velocity of the shot on leaving the gun,

$$v=\frac{1783}{\sqrt{r\mathrm{D}'}}\sqrt{\left(na\ \text{hyp. log.}\ \frac{b}{a}+a-b\right)}$$

On comparing the results of the formula with those obtained from experiments made with the Ballistic pendulum, Dr. Hutton found that the expansive force of powder varies, with the quantity employed, from 1776 times to 2300 times the pressure of the atmosphere; allowance being made for the loss of force occasioned by the vent and by windage. Those numbers express the values of n in the formula.

From the numerous experiments made with the machine above mentioned between the years 1784 and 1791, Dr. Hutton concludes that the initial velocities of shot are directly proportional to the square roots of the weights of the charges, and inversely proportional to the square roots of the weights of the shot (the guns being similar to each other); and he gives for the initial velocity in feet the formula $\mathrm{v}=1600\sqrt{\frac{2c}{w}}$; where c is the weight of the charge, and w that of the shot. Dr. Gregory's formula, founded on more recent experiments, is, $\mathrm{v}=1600\sqrt{\frac{3c}{w}}$, which with reduced windage is more nearly correct. It must be admitted however that some uncertainty still exists respecting the value of v, partly on account of variations in the quality of the powder, and partly in consequence of the different degrees of windage; and these are the chief causes of the want of agreement between the experimented and calculated ranges of shot. This however is not in general greater than that which has been observed between ranges obtained from different trials when made in like circumstances.

The resistances actually experienced by a shot in passing through the air were, in 1789, made the subjects of experiments with the Ballistic pendulum and the whirling machine as before mentioned, and are described in Hutton's Tracts. The resistances were determined from the general formula,

$$r=\frac{v\,v'}{32\,s}w,$$

Where r = the required resistance in pounds or ounces.
v = the mean between two velocities, namely, the first velocity and the velocity with which the ball strikes the pendulum.
v' = the difference between these velocities.
s = space passed through.
w = weight of the body in pounds or ounces.

The above formula is obtained thus, $t = \frac{3}{r}$ nearly; and $1'' : t :: 32 : 32t$ = the velocity generated or destroyed by gravity in (t) time; therefore, $32t : v' :: w : r = \frac{v'}{32t}$ but $t = \frac{s}{v}$ $\therefore r = \frac{v'v}{32s}w$ = the force of resistance. From the results of the experiments, which though not sufficient to establish a perfectly true theory, enable us to obtain results sufficiently accurate for all practical purposes, it appears that the resistances are in rather a higher ratio than the squares of the diameters of the shot; and, as examples of the amount of the resistance, it may be observed, that a ball weighing 3 lbs., when moving at the rate of 500 feet per second, was opposed by a force equal to about 35½ lbs.; and, when moving with the velocity of 1700 feet per second, by a force equivalent to the pressure of above 154 lbs. It was found also that there is a gradual increase in the exponent of the resistance as the velocity increases, probably on account of the partial vacuum behind the ball. When the motions were slowest, the resistance was nearly proportional to the square of the velocity; and when the shot moved at the rate of 1500 feet per second, that exponent seemed to have attained its maximum, the resistance being then nearly as the 2⅛ power of the velocity. Beyond that rate of motion the exponent of the resistance gradually decreased.

In the preceding formulæ the height h, or that which is due to the initial velocity, is by the theory of forces equal to $\frac{\mathrm{V}^2}{2g}$; where V represents the initial velocity, and g, as before, $= 32\frac{1}{6}$ feet. To obtain the value of H it must be observed that, from hydrostatical principles, we have $\frac{1}{2}r^2\pi p\,\mathrm{D}$ for the resistance experienced in moving through a fluid by a body which is terminated in front by a hemispherical surface; where r is the semi-diameter of the sphere, D is the specific gravity of the fluid (air in the present case), and p is a co-efficient which must be determined by experiment. Then the mass of the shot being equal to $\frac{4}{3}r^3\pi\mathrm{D}'$ (where D′ is the specific gravity of the shot), dividing the former of these terms by the latter we have $\frac{3\,\mathrm{D}p}{8\,\mathrm{D}'r}$ for the retardative power of the resistance. Hence $\sqrt{\frac{8g\,\mathrm{D}'r}{3\,\mathrm{D}p}}$ becomes the terminal, or constant velocity, with which the shot would descend in the air when the resistance of the latter becomes equal to the accelerative power of gravity.

Now, in the preceding investigations, $\frac{1}{\mathrm{H}}$ was made to represent $\frac{\mathrm{A}.\mathrm{D}p}{\mathrm{M}}$; therefore, substituting for A its equivalent $r^2\pi$, and for M its equivalent $\frac{4}{3}r^3\pi\mathrm{D}'$, we shall get $\mathrm{H} = \frac{4r\mathrm{D}'}{3\,\mathrm{D}p}$; which, being compared with the above expression for the terminal velocity, is evidently the height due to that velocity, or the space through which a body must descend from rest, *in vacuo*, to acquire that velocity.

Dr. Hutton, having formed a table exhibiting the resistances experienced by shot when moving with different velocities, determined from it, by simple proportions, the values of the terminal velocities for solid shot weighing from 1 lb. to 42 lbs. (Tract 37, art. 69.) And in the same Tract (art. 122) he has given a table of terminal velocities for several natures of shells. These last velocities necessarily differ from those of solid shot, because the shells have less weight than solid shot of equal diameters. Assuming therefore that the internal diameter is $\frac{7}{10}$ of the external diameter of a shell, he estimates the ratio of the weights of the solid and hollow shot to be as 1·42 to 1; and, in order to express the terminal velocities of the latter he diminishes those of the former in that ratio. Hence the formula for the terminal velocity of a shell should be

$$\sqrt{\frac{8gr\frac{\mathrm{D}'}{1\cdot42}}{3\,\mathrm{D}p}}, \text{ or } \sqrt{\frac{5\cdot63\,gr\mathrm{D}'}{3\,\mathrm{D}p}};$$

and from the numbers given in the tables it appears that p may be considered as equal to 0·6849. On putting this formula in numbers, r and g must be expressed in terms of the same denomination.

It is easy to conceive that by increasing the charge to a certain amount the velocity will also be increased, and that when the quantity of powder is so great that the ball is driven out of the barrel before the whole has time to act upon it, the velocity must become less. There is evidently therefore a certain quantity of powder which will produce the greatest possible velocity; and this may be determined by making the differential of the expression above found, for the velocity, equal to zero, the length a of the space occupied by the charge being considered as variable. Dr. Hutton makes the charges for producing the maximum velocity to vary with the length of the gun: thus the length of the bore being equal to 10, 20, 30, 40, and 50 calibres, the numbers 0·5, 0·81, 1·09, 1·28, and 1·43 will respectively express the weight of the powder in terms of the weight of the shot. (Tract 37, art. 189.)

The service charges, in terms of the weight of the shot, are—

For brass and iron guns . . .	$\frac{1}{3}$
For brass howitzers	$\frac{1}{6}$
For carronades	$\frac{1}{12}$

From experiments which have been carried on at Woolwich, on Sutton Heath, and in France, the following very brief abstract of the circumstances attending the flight of projectiles has been drawn up :—

I. Experiments with solid shot fired at point blank.

Iron Guns.			Brass Guns.			Carronades.		
Height of the Gun above the ground = 8 ft.			Height of the Gun above the ground = 4 ft. 6 in.			Height of the Battery above the ground = 8 ft.		
Weight of Shot in lbs.	Charge in lbs.	Range in yds.	Weight of Shot in lbs.	Charge in lbs.	Range in yds.	Weight of Shot in lbs.	Charge in lbs.	Range in yds.

II. Ricochet practice in 1821.

Solid Shot.

Nature of Ordnance.	Elevation in degrees.	Charge.	Range in yards.	Number of grazes.
24 Pounder Iron gun	11 6 3½	8 oz. 1 lb. 2 lb.	400 600 800	18 10 8
18 Pounder Iron gun	6½ 7	9 oz. 1 lb.	400 800	27 10
12 Pounder Iron gun	6¼ 6½	6 oz. 12 oz.	400 800	19 10
68 Pounder Carronade	6¼	2 lb.	600	5
24 Pounder Brass Howitzer	4¾	1 lb.	600	2

Shells.

10 Inch iron howitzer wt. of shell 92 lbs.	5 9¾	4 lbs. 2½ lbs.	600 600	2 4
8 Inch iron howitzer wt. of shell 46 lbs.	9½ 6¾	1 lb. 2½ lbs.	400 800	12 5
5½ Inch howitzer wt. of shell 16 lbs.	9	12 oz.	600	4
24 Pounder howitzer wt. of shell 16 lbs.	4¾	9 oz.	400	16
12 Pounder howitzer wt. of shell 8 lbs.	8	oz.	600	4
68 Pounder Carronade	8½	1½ lb.	600	6

From the result of the experiments it appears that at a range of 400 yards, with a weight of powder equal to $\frac{1}{42}$ of the weight of the shot, about two-thirds of the rounds took effect: at 600 yards, with charges from $\frac{1}{33}$ to $\frac{1}{20}$, from one-half to one-third took effect; and, at 800 yards, with charges from $\frac{1}{24}$ to $\frac{1}{12}$, from one-third to two-fifths took effect. It is hence concluded that ricochet batteries should, if possible, be at distances between 400 and 600 yards from the object: at a greater distance much of the ammunition would be uselessly expended. Also that, with both shot and shells, the best elevation for enfilading a work is from 6° to 9° above the crest of the parapet of the work.

III. Practice with a 10-inch mortar, Sutton Heath, 1811. The elevation = 45° and the weight of the shell = 96 lbs.

Practice with a French 12-inch mortar, Toulon, 1830. The elevation = 45° and the weight of the shell = 162 lbs.

Charge in lbs.	Time of Flight.	Range in yards.	Charge.	Time of Flight.	Range in yards.

The effects of shot in penetrating any material form a subject of great importance in military engineering, as a knowledge of those effects can alone afford data for constructing walls and roofs capable of resisting the momenta of the vast masses which, during a siege, may descend upon or be projected against them. And in order that such effects may be made the objects of scientific investigation, the resistance which the material opposes must be considered as a uniformly retarding force, like that which gravity would exert against a shot fired vertically upwards: then the depth penetrated will correspond to the space which would be described by a body, when subject to an accelerative force equal to that retardative force, in the time that it would acquire a velocity equal to that of the impact, and the time of the penetration may be considered as equal to that in which such velocity would be acquired. By the theorem of uniformly accelerated motions we have F varies as $\frac{w\,v^2}{s}$ (where F is the accelerative or retardative force, w is the weight of the body, v the velocity with which it is moving, and s the space moved through).

Now, if G represent the force of gravity:

g = 32⅙ feet, or the velocity generated in one second by the force of gravity,

$\frac{g}{2}$ = the space or height due to that velocity,

v = the given velocity of impact,

s = the depth of the impression. Then

$G : \frac{w\,g^2}{\frac{g}{2}} :: F : \frac{w\,v^2}{s}$; whence $F = \frac{v^2 G}{s.2g}$ which is the force of resistance exercised by the material.

If G be supposed to be equal to unity, we shall have $F = \frac{v^2}{s.2g}$ and this value of F expresses the ratio of the retardative force to that of gravity; consequently, representing the latter by the weight w of the shot, the force of resistance should be expressed by $\frac{w\,v^2}{s.2g}$.

In Sir Howard Douglas's 'Treatise on Naval Gunnery' there are recorded the following results of experiments on the penetration of an 18-pounder shot into a butt made of beams of oak; namely, with charges of 6 lbs., 3 lbs., 2½ lbs., and 1 lb., the depths of the penetrations were 42 inches, 30 inches, 28 inches, and 15 inches respectively; the velocities are 1600 feet, 1130 feet, 1024 feet, and 656 feet respectively; and from these data the mean value of F will be found to be 138701. This number expresses the resistance of the oak, in pounds, against a surface equal to the area of a section through the centre of the shot; and, by reduction, it becomes equivalent to 912190 pounds exerted on one square foot.

Similar experiments made at Metz by firing 24-pounder shot against butts of fir (the numbers being reduced to English denominations) gave 475070 pounds for the resistance exerted on a square foot.

At Woolwich, in 1835, two 24-pounder shot were fired with a velocity of 1390 feet per second against a wall of concrete, into which they penetrated to the mean depth of 3 feet 10 inches; whence, by the above formula, we have F=188047 pounds; and, consequently, the resistance on a square foot is equal to 1013730 pounds. From a like experiment made at Metz it was found that the resistance opposed by a wall of oolitic stone might be expressed by 1394800 pounds (English) on an equal surface.

The French engineers, agreeably to the theoretical determination of M. Prony, suppose the volume, instead of the depth, of the space penetrated to be proportional to the term wv^2; but when that space is cylindrical, the hypothesis will evidently be identical with that which has been above stated. Dr. Hutton finds that, on firing into wood, the depths of penetration, when high charges are employed, are in a lower ratio than the squares of the velocities, and nearly proportional to the velocities simply: this he supposes to depend on the resistance caused by the elasticity of the fibres which are driven before the ball during the time of penetration.

Mr. Robins, in his work and various tracts on gunnery, was the first to point out the important effects of rotation in producing deviations in the line of flight of cannon balls. This rotation may be caused both by the balls not fitting exactly to the bore of the gun, when the friction being greater on one side than on the other would offer a greater resistance to its motion on that side, and, secondly, by the density of the ball not being uniform. When the centres of gravity and figure do not coincide, the forces, that is, the pressure of the gases generated by the powder, acting on the ball to move it, would act unequally on each side of the centre of gravity, except when the line joining the centres of gravity and figure is coincident with the axis of the bore, and would, by the theory of parallel pressures, produce (besides exerting its whole pressure in the motion of translation in a line through the centre of gravity parallel to the axis of the bore) a motion of rotation round a horizontal axis passing through the centre of gravity, due to the couple whose arm is the line joining the centre of gravity and centre of the figure, and whose force is the same pressure acting through the centre of the figure. Though the constraint due to the bore of the gun would cause the direction of the rotation to be that in which the centre of form was moving relatively to the centre of gravity (which latter while passing through the bore must be performing equal oscillations about the centre of form in a plane containing the centre of gravity and axis of the bore) at the moment of leaving the bore, depending therefore on its length; yet as from the velocity of rotation being proportionately small to the velocity of translation, there is not time for a complete oscillation in the length of the bore, in practice the direction of rotation depends entirely on the relative positions of these points when placed in the bore of the gun. Thus, if when the ball is first acted on, the centre of gravity is in a vertical line below the centre of form, the rotation in leaving the bore will be round a horizontal axis passing through the centre of gravity, and causing the anterior part to move downwards. If the positions of the centres of gravity and form be reversed, the motion of the anterior part of the ball will be upwards, and in the same way to the right or left.

If a perfectly smooth homogeneous sphere rotate in the air, there is nothing to produce movement in the position of its centre of gravity on an axis through which it is rotating; and when rotation is combined with translation there is nothing to cause deflection from the line in which it is translated. But if the surface be not smooth, when being translated, the air being denser in front than behind, depending on the velocity of translation, the friction will not be symmetrical on both sides the axis of rotation, but being greater on the anterior surface will tend to produce deflection in the centre of the sphere in a direction contrary to the one in which this surface is moving. But on the other hand, one half of the surface is rotating in a direction *with*, and the other half in a direction *contrary to*, the motion of translation, and the actual velocity of the former half through the air being greater than that of the latter from its position, prevents its escape, and causes a greater density in the air on that side. The resistance to motion being greater in this direction than in the other, there is a tendency to produce deflection in the centre of the sphere in the direction in which the surface is rotating *contrary to* the motion of translation; that is, in the direction in which the anterior surface is rotating, and this latter tendency is found in practice to overcome the former, and the shot is deflected in the direction in which the anterior surface is rotating. When a shot is excentric, that is, where the centres of gravity and figure do not coincide, and the ball is rotating round an axis through the centre of gravity, there is not only this friction, but a displacement of air equal to the figure contained between the sphere whose radius is the shortest distance from the centre of gravity to the exterior and the figure of the shot itself. The above described effect is then immensely exaggerated; in fact, if there were no friction, the resultant normal pressures would in this case make an angle with the direction of translation, and therefore cause deflection. Experiments were made in 1851, at Shoeburyness, with shot and shell made excentric by removing portions of the metal and replacing them with a heavier or lighter body. The direction of the line joining the centre of gravity and centre of figure was then determined by floating the shot in mercury. By this means they could be strapped to wooden bottoms in any position desired. An increase of upwards of 900 yards in the range was obtained with these excentric projectiles over concentric ones at angles of 20° to 28° and 32°, and deflections proportionally large according to the relative positions of the centre of gravity and figure of the shot when placed in the bore of the gun as above described. It is evident that the deflection of spherical shot from smooth bored guns is principally, if not wholly, due to the varying rotations which arise, and which produce deflections not in planes making angles with the direction of the piece when the deflection would be proportionate to the distance, but in incurvated lines, as stated by Robins and proved by his experiment with the bent barrel. In a rifle [RIFLE] we have the means of impressing on the projectile a rotation round an axis coincident with the line of flight; when the resistances being equal round the pole of rotation, no deflection can be produced while the axis remains coincident, and any casual irregularity on the point or surface is compensated for by being constantly shifted round from one side to the other. Rifling, again, gives us the power of using elongated bullets (cylindro-conical), which are kept point foremost by their rapid rotation, which has the tendency of always keeping the axis of rotation parallel to its original direction; and it will be easily seen from the previous investigations on the resistance of the air, what a greatly increased power of maintaining its initial velocity is possessed by a ball which, with the same surface of resistance, has double or treble the weight of another. These are the reasons for the enormously increased ranges and accuracy obtained with the Whitworth and Armstrong guns, to which we shall have again occasion to refer under RIFLE.

GUNPOWDER, a composition with the explosive power of which every one is more or less acquainted. The date of its invention is involved in obscurity. It has been said that it was used in China as early as the year A.D. 85, and that the knowledge of it was conveyed to us from the Arabs on the return of the Crusaders to Europe; that the Arabs made use of it at the siege of Mecca in 690; and that they derived it from the Indians.

Sir George Staunton observes that "the knowledge of gunpowder in China and India seems coeval with the most distant historic events. Among the Chinese it has at all times been applied to useful purposes, as blasting rocks, &c., and in the making of fireworks; although it has not been directed through strong metallic tubes, as the Europeans did soon after they had discovered it."

Roger Bacon has been supposed to allude in an enigmatic way to the composition and explosive force of gunpowder; and about 1336 Berthold Schwartz, a monk, is said to have also discovered the mode of manufacturing it.

Gunpowder consists of a very intimate mixture of nitre, or nitrate of potash, charcoal, and sulphur. Theoretically, the proportions of these ingredients ought to be as follow:—

	Equivalent weight.	Per-centage amount.
1 equivalent nitrate of potash . .	101·11	74·8
3 equivalents carbon	18·00	13·3
1 equivalent sulphur	16·00	11·9
	135·11	100·0

It is remarkable that these proportions have been nearly attained empirically in the best descriptions of gunpowder, as seen from the following table:—

	English.	French.	Prussian.
Nitrate of potash . . .	75·0	75·0	75·0
Charcoal	15·0	12·5	13·5
Sulphur	10·0	12·5	11·5
	100·0	100·0	100·0

The suddenness and intensity of the explosion depends upon the amount of sulphur, which is on this account increased in blasting-powder, the composition of blasting-powder being:—

Nitrate of potash	65
Charcoal	15
Sulphur	20
	100

This large amount of sulphur would cause the corrosion of fire-arms, and consequently for war and sporting purposes the quantity is diminished.

The ingredients must be of the greatest attainable purity; and the nitre is fused before use, in order to expel the last portion of water, which seems however scarcely necessary for any other purpose than the exact ascertainment of its quantity, inasmuch as the mixture is subsequently wetted. The charcoal, either of alder, willow, or dog-wood, is prepared, not in the usual method, but in iron retorts; and the sulphur is the volcanic kind imported from Sicily, and is refined by melting or subliming.

When the several ingredients are prepared, they are separately ground to a fine powder, and mixed in the proper proportions. The composition is then sent to the gunpowder-mill, which consists of two stones vertically placed, and running on a bed-stone. On this bed-stone the composition is spread, and wetted with as small a quantity of water as will, together with the revolutions and weight of the runners, bring it into a proper body, but not into a paste. After the stone runners have made the proper number of revolutions over it, and it is in a fit state, it is taken off and sent to the corning-house to be corned or grained; here it is first pressed into a hard and firm body, broken into small lumps, and the powder is then grained by these lumps being put into sieves, in each of which is a flat circular piece of lignum vitæ. The sieves are made of parchment skins, having round holes punched through them; several of these sieves are fixed in a frame, which by machinery has such a motion given to it as to make the lignum vitæ runner in each sieve go round with velocity sufficient to break the lumps of powder, and force them through the sieves, forming grains of several sizes. The grains are separated from the dust by proper sieves and reels; they are then hardened, and the rougher edges taken off by being run a sufficient length of time in a close reel, which has a proper circular motion given to it.

The gunpowder, thus corned, dusted, and reeled (which is called glazing, as it puts a small degree of gloss on it), is sent to the stove and dried; care being taken not to raise the heat so as to dissipate the sulphur. The heat is regulated by a thermometer.

A powder-mill is a slight wooden building with a boarded roof. Only about 40 or 50 pounds of composition are worked at a time, as an explosion will sometimes happen from the runners and bed-stone coming in contact, and from other causes. These mills are worked by water or horses.

The theory of the action of gunpowder is this:—That particle of it on which a spark falls is immediately heated to the temperature of ignition; the nitre is decomposed, its oxygen combines with the charcoal, whilst the sulphur unites with the potassium of the nitre, thus:—

$$\underbrace{KONO_5}_{\text{Nitre.}} + S + 3C = \underbrace{KS}_{\substack{\text{Sulphide of}\\\text{potassium.}}} + N + \underbrace{3CO_2}_{\substack{\text{Carbonic}\\\text{acid.}}};$$

this combination extricates as much heat as is sufficient to inflame successively, though rapidly, the remaining mass. The cause of the expansive force of gunpowder is the production of carbonic acid and nitrogen gases; and these being liberated at a very high temperature, the effect is greatly increased. Gunpowder is thus expanded about 4000 times at the moment of explosion. According to Gay-Lussac, every 100 volumes of the gas produced consist of 53 parts of carbonic acid, 5 of carbonic oxide, and 42 of nitrogen. The carbonic oxide is formed by an excess of charcoal, as in the English powder. The solid remaining after the combustion is principally sulphuret of potassium; but it is evident that the proportions and nature both of the gaseous and solid products of the combustion must depend on the composition of the gunpowder.

Gunpowder may be fired by the electric spark, and by percussion. If it be mixed with powdered glass, or any other hard substance, and struck with a heavy hammer on an anvil, it almost always explodes. It readily burns under water, and by using a slowly burning powder, such as squibs are filled with, may be inflamed in a tube of copper, and the gaseous products of the combustion may be collected in a glass jar filled with and inverted in water in the pneumatic trough.

In ascertaining the goodness of gunpowder, which is done by determining its strength, an *eprouvette* is employed to measure its projectile force. This is a small strong barrel, in which a given quantity of the powder is fired, and the comparative expansive force is measured by the action exerted on a spring or weight.

A ready but not a very accurate way of analysing gunpowder is to wash out the nitre of a given weight by water, weigh the residue, which will show the quantity of nitre dissolved, and boil it in a solution of potash; the residue, after washing and drying, will be the charcoal, and its weight taken from that left after the action of the water will show the quantity of sulphur dissolved by the potash.

GUNTER'S LINE; GUNTER'S SCALE. [Sliding Scale.]

GUTTA-PERCHA MANUFACTURE. Few substances applicable to the arts have sprung up so rapidly into extensive use as gutta-percha. Twenty years ago it was wholly unknown in Europe. In 1842, Dr. Montgomerie, a resident at Singapore, looking at a native wood-cutter while at his employment, was struck with the peculiar appearance of the handle of the axe; it was formed of some material not familiar to him. On inquiry, Montgomerie found that the substance of which the handle was made could be moulded into any form by dipping it into boiling water until it became soft, and that it speedily resumed its tough and rigid condition when removed from the water. He next ascertained that the substance resembled caoutchouc in this: that both exude from between the bark and the wood of certain forest trees. The natives around Singapore called it by a name which, with an addition, soon became *Gutta-percha*. Dr. Montgomerie sent specimens, in various stages of preparation, to the Society of Arts in London. Independently of Dr. Montgomerie, however, a discovery of the tree and the gum was also made by Mr. Thomas Lobb, who in 1842-3 was travelling in the east as agent for Messrs. Veitch, of Exeter. Those enterprising botanists and florists employed their agent to procure new or rare plants for transmission to England; and while on his rambles, Mr. Lobb acquired a knowledge of gutta-percha, as a gum which exudes from trees. When the small pieces reached the Society of Arts, Mr. Whishaw and Mr. Hancock experimented on them, with a view to discover their useful qualities; pipes, lathe-bands, and sheets were soon produced in a rough way, and a basis was obtained for an important addition to our materials for manufactures.*

It gradually became ascertained that the gutta-percha tree abounds in the Malayan Peninsula, in Borneo, and in various islands of the Eastern Archipelago. The chiefs of those islands, or portions of them, contrive to obtain a profit out of the trade; but there is still sufficient left to allow remuneration to all else concerned. For about sixteen years the trees have eagerly been cut down as a means of obtaining the gum; and however this may be regretted as a wasteful proceeding, it nevertheless cleared the ground for future settlers in those islands. Europeans are, however, teaching the natives how to obtain the sap without cutting down the tree. The tree belongs to the *Sapotaceous* or gum-exuding group; the wood, soft and spongy, is not of much use; the fruit yields a thick oil, which the natives mix with their food, and from which an ardent spirit can be obtained. The sap, which forms the most valuable product, circulates in small vessels between the bark and the wood; by tapping, or cutting notches in the branches at certain seasons, it flows out without endangering the life of the tree. How far the process can be so managed as to obtain a continuous or periodical supply from the same tree, is a problem not yet solved. The sap flows out into vessels held underneath. Before it is consolidated by the action of the air, the gatherers knead it into lumps by the hand or by a piece of wood; it is brought into any shape at pleasure, but usually comes to market in the form of roundish lumps, eight or more inches in diameter. Most of the gutta-percha of the Eastern Archipelago comes to Singapore as the chief market; and the buyers too often find it adulterated with wood, stone, and other impurities, to increase the weight; there is also much refuse of bark, leaves, and dirt mixed up accidentally with it. On these accounts, all the specimens are narrowly scrutinised on reaching the London market, to determine their net value when freed from all impurities.

---

* Credit has been given, in most of the technological and scientific publications, to Dr. Montgomerie, as the person who first introduced (in the way noticed) gutta-percha to the attention of Europeans. In 1858, however, a claim was put in for Don Jose d'Almeida; who, in 1842, bought some of the gum from the natives of Singapore, brought it to England, gave a portion to a fellow-passenger, and sent the remainder to the Royal Asiatic Society.

Before gutta-percha can be applied to any of the numerous purposes for which it is now known to be valuable, it requires a great deal of preparation. The preparatory processes are peculiar, on account of the remarkable toughness of the substance. The masses are first cut into slices, by means of a wheel provided with knives or blades; the wheel revolves two or three hundred times in a minute, and the slices are cut as if by a turnip cutter. If there are any stones or other hard impurities in the lumps, the slicing detects it; the cutting edges are blunted, and the adulterants require to be removed. The gutta-percha varies much in colour, consistency, and other qualities, even in the same mass; and a thorough mixing becomes necessary. The slices are thrown into a tank of water, heated by steam; the dirt and heavy impurities fall to the bottom, leaving the gum as a pasty mass. The gum is then transferred to a rotating machine, where sharp jagged teeth rend and tear it asunder with great violence; the fragments fall down into water, where they float. After another softening in hot water, the gutta-percha is transferred to a kneading trough; this is a kind of cylinder, kept hot, in which revolving drums knead and roll the substance most completely, rendering it as homogeneous as possible in all parts. The shapeless but purified mass is next brought into certain forms, preparatory to its useful application in the arts. These forms may be blocks, slabs, sheets, or tubes. In forming sheets, the gutta-percha is passed between steel rollers, placed at a distance apart corresponding with the thickness of the sheet to be made. By the adjustment of a few knife edges, these sheets may be cut into bands or strips of any width. In making tubes or pipes, the gutta-percha is softened, and passed through heated iron cylinders, where it is reduced to size and form by a kind of wire-drawing process.

To estimate the actual and prospective uses of this singular substance, we must take note of its properties. The toughness of gutta-percha, differing from the elasticity of caoutchouc, and the facility with which it may be softened by heat, render it fitted to receive and retain any form that may be given to it. It is very easily pressed in moulds, while in a warm and plastic state. Whether wet or dry, its uses are confined to cold purposes, as it is soon affected and thrown out of shape by heat. For many purposes, naphtha and other inflammable liquids act as cements and solvents for it. Its surface is susceptible of being so prepared as to receive paint, gilding, japanning, burnishing and other decorative modifications. Its remarkable relation to electricity renders it an invaluable substance for coating telegraphic wires. Its stubborn resistance of the corroding action of many powerful acids, alkalies, and salts, fits it for use in vessels and pipes for chemical operations. Its impermeability to water has brought it largely into use as a sheeting for damp walls and other places.

The works of the Gutta-Percha Company, in the City Road, are the largest in any country; and a list of the articles made in that establishment would show into how many departments of every-day life the use of this substance has extended. Such a list need not be given here; for every week would add something to its length; but the uses might easily, if necessary, be grouped into such headings as *domestic*, *surgical*, *chemical*, *manufacturing*, *agricultural*, *electrical*, *maritime*, *engineering*, and *ornamental*. The gutta-percha, when applied to these uses, is in form of a sheet, a strip or ribbon, a rod, a tube, a cord, a cloth, &c.; and many processes, especially stamping, are employed to fashion the gutta-percha into the desired shapes. The gum possesses much value as a material for water-pipes; it is strong and tough; it resists frost; it leaves the water as pure as it finds it; it will bear a great amount of friction and hard usage; it resists the action of marine insects; it is conveniently flexible as a material for hose for watering gardens and roads, and sprinkling malt; and it is recommended by many physicians as a substitute for lead pipes, on account of the deleterious nature of the latter. A gutta-percha tube three-quarters of an inch in diameter, and one-eighth of an inch thick, has been found to bear an internal pressure of 500 lbs. on the square inch, without bursting; it yielded a very little, and then resumed its original form. The Americans, in carrying the water of the great Croton aqueduct into New York, laid down a gutta-percha pipe, a thousand feet in length, along the bed of an intervening river, where it was kept down by anchors; the pipe bore the pressure of the aqueduct water within it and the river water around it, as well as the weight of the moorings and the friction of the bed. In a wholly different department of application, gutta-percha is singularly valuable; no other known substance equals it for *acoustic* properties. The sonorous vibrations of the air are less stifled in a gutta-percha tube than in one made of any other substance; hence the extensive use of this material for speaking-tubes, ear-trumpets, domestic telegraphs, &c.; it assists the hearing of partially-deaf persons, and transmits the sound of the voice to a distance which would otherwise render it inaudible even to sensitive ears. The electric insulating properties of gutta-percha are now well known, as among the most indispensable conditions for telegraphic communication. In land electric-telegraphs, there is no occasion to coat the copper-wires with gutta-percha, provided the supporters are made sufficiently insulating; but for the submarine wires such an envelope is necessary, to prevent the electric current from diffusing itself in the surrounding water. Wires coated with gutta-percha have also been found serviceable for igniting blasts of powder, in great engineering operations. Gunpowder has been blasted at one end of a wire 70 miles long, by a galvanic current sent in at the other end. In its form as a sheet, gutta-percha is used in many situations in contact with cold water, on account of the ease with which it can be cut and cemented, and the way in which it resists moisture. It has in this way been successfully applied as a lining for cisterns; as a material for water-buckets and valves; and as an extra sole for boots in wet weather. Some of the boats made of gutta-percha have presented very remarkable qualities. Mr. Snow, who had charge of a gutta-percha boat in the arctic ship Prince Albert, said:—"The severest trial it endured, and endured successfully, was in both my visits to Whaler Point, Port Leopold. To those unaccustomed to the nature of such ice as was there met with, it will be impossible fully to conceive the position a boat was placed in. The mere transit to and fro, among loose masses of ice, with the sea in a state of quiescence, would have been quite enough to prove the value of gutta-percha boats; but when, as in the present case, those masses were all in restless agitation, with a sea rolling in upon an opposing current, it might have been well excused—and without deteriorating from the previously-attested goodness of the article—if it had not been able to resist the severe shock it received. . . . Sliding through and over the ice; sometimes lifted completely out of the water by the sudden contact of a restless floe, and at others thrown sideways upon an adjoining craggy piece, I think it would have been next to impossible for any other kind of boat to be otherwise than crushed or stoved on the instant." The name of Gutta-Percha Inlet was given to the place where this boat had rendered such valuable service.

Widely different from any of the above-named uses, are those in which gutta-percha is employed as a material in decorative art. It is fitted for such purposes chiefly in virtue of the facility with which it takes the impress of a stamp or mould when heated, and the correctness with which it maintains that impressed form when cold. The mould may be of metal, wood, or almost any other material. One of the most frequent modes of producing the casts is this. A piece of sheet gutta-percha is laid upon a steam-heated slab of marble or stone; when sufficiently softened, it is laid upon or in the mould, a counter-mould is laid upon it, and a screw-press finishes the process. If the pattern be in very bold relief, a hydraulic-press may be necessary; but in most cases a hand-press supplies a sufficient degree of force. Some years ago the Irish Patent Office adopted gutta-percha as a material for the seals of patents, on the ground that it gives bold and sharp outlines, and is free from the odour, brittleness, and greasiness of the yellow wax previously employed; but this novelty has, we believe, not been retained by the commissioners of patents. It is by a process of pressing in moulds that a vast number of articles are made in gutta-percha, useful in their application and ornamental in their appearance. Sometimes a dextrous workman will give a clouded or grained or veined appearance, by availing himself of the different tints which different pieces of gutta-percha present; when the surface is polished, this diversity gives rise to much beauty of appearance. More closely associated with fine arts are those processes in which gutta-percha assists in a kind of engraving or transferring—for which see ENGRAVING; PRINTING; PHOTOGRAPHY.

In all that has been said hitherto concerning gutta-percha, the use of that substance by itself is implied; but much ingenuity has been displayed in producing combinations. One among the many modes of employing gutta-percha as a material for models, moulds, medallions, &c., is that of Duthoit, a French inventor. The gutta-percha is first dissolved in naphtha, then filtered, and then put into a still, with the addition of oxide of zinc, sulphate of barytes, amianthus, and one or two other substances. When the mixture has been well stirred, heat is applied, and the volatile elements driven off. The composition being taken out of the still, is ready for use. Colouring matter is either put into the still with the other ingredients, or it is mixed afterwards by masticating the composition with it, in presence of warm water containing a little soda. The substance thus prepared is suitable to make not merely models and moulded articles, but also tissues, artificial-flowers, and a substitute for leather. If diluted with naphtha or benzole, the composition may be used as a liquid paint. Some of the compositions are intended to liquefy rather than harden the gutta-percha: such as that of dissolving the gum in carburet of hydrogen, which produces a liquid useful for removing grease, making good varnish, and improving the surface of inking rollers.

Many inquiries of a peculiar character have recently been made into the properties, purity, excellences, and defects of gutta-percha, under various circumstances. The telegraphic uses of this substance are among the most important: for whether the wires pass through the sea or underground, they equally require to be protected by a covering of gutta-percha, or some other insulating substance; and it is very essential that this insulation should be proof against all the enemies who are likely to attack it. One of the important circumstances connected with the use of gutta-percha for telegraphic purposes, is the tendency of the substance to become heated when closely packed. Nearly 700 miles of coated wire were sent to India in 1853, packed in deal boxes; it was found on arrival to have been in a soft state during the voyage, allowing the wire in some places to squeeze through the gutta-percha; and also that the envelope had become rather brittle after the cooling when opened. When packed closely for some time, the substance becomes heated, absorbs twenty or more per cent. of oxygen, and is chemically an altered substance, losing much of its insulating power.

Another inquiry, connected with the telegraphic uses of gutta-percha, relates to a peculiar and little understood kind of decay to which the gum is subject, tending to destroy its useful qualities. In the autumn of 1856, some of the British Electric Telegraph Company's wires ceased to work south of Berkhampstead. Mr. Edward Highley made a careful examination of the circumstances, with a view to discover the cause. The wires were enclosed in a wooden trough or trunk, about two feet below the surface of the ground. He found that wherever the wires passed near oak-trees, the troughs and the gutta-percha were decaying; but the vicinity of other trees did not seem to produce the same injurious result. On examining more closely, he detected a whitish-looking substance, resembling the spawn of the mushroom or some other fungus; it spreads around the dead roots of the oak-trees, and around the trough, carrying decay with it; and the gutta-percha at those places was quite rotten. Portions of new trough and gutta-percha had in this way been rendered useless in the short space of six months. Under each tree was found a yellowish-green fungus, luxuriantly growing; but it was not quite apparent whether the white substance was a distinct plant, or the spawn or mycellium of the yellowish-green fungus. The subject was rightfully regarded as of much importance to the owners of subway or subterranean telegraphs; and Mr. Highley was requested to continue his investigations. During the year 1857, he exposed several specimens of sound gutta-percha to the action of the mycellium of a fungus, namely, the *Agaricus campestris*, in a bed of soil of sufficient depth; and in four months he found the gutta-percha completely eaten away.

Irrespective of all inquiries concerning the practical application of gutta-percha, are others relating to an extension of the field of supply. Already it is known that three kinds reach the market, called gutta-*percha*, gutta-*tuban*, and gutta-*girek*, differing very little in properties; and it is considered that many varieties of trees, growing in tropical countries, may probably yield a juice or sap which, carefully collected and subjected to manufacturing purposes, might weaken monopoly by extending the use and enlarging the conditions of supply. The Society of Arts, in 1852, offered a premium for the importation of any new substance which could be used as a substitute for gutta-percha. Partly arising from this offer, and partly from the natural importance of the subject, many vegetable juices have from time to time been brought under public notice. Mr. Meadows Taylor, of Hyderabad, wrote to the 'Journal of the Agricultural and Horticultural Society of India' a description of the properties of the *Muddar* plant of India, in reference to the use of its juice as a substitute for gutta-percha. Dr. Riddell, of the Nizam's army, found that the milky juice or sap of the muddar, when exposed to the air, dries tough and hard. It is a common hedge-plant, very abundant in the Nizam's dominions. In order to test the juice in various ways, Dr. Riddell collected and solidified some of it. It was found to be quite soluble in spirit of turpentine, producing a good varnish. When heated with acids, it became affected almost exactly in the same way as gutta-percha. It softened in hot water sufficiently to take the impression of a seal, and to be fashioned into cups. The natives of Rajpootana have long employed it as a waterproof varnish. The tree will grow on the poorest land, and yields a fibre available as a substitute for hemp, and therefore deserving the attention of commercial men. Still later (in 1856), Mr. Osborne, of the East India Company's Civil Service, sent to the Society of Arts specimens of desiccated juices which he had obtained from trees near Goruckpoor. When procured, the juice was nearly milk-white, with a satin-like texture; it gradually hardened in the air, and softened again in hot water. In the semi-fluid state it could be easily kneaded and extended; or used for the impression of a seal, which remains in its proper shape when cold. It effaced pencil marks, like india-rubber, but soiled the paper. The exterior became gray after a time. The gum was scarcely affected by cold water. When exposed to the flame of a candle, it melted and inflamed like sealing-wax. It dissolved completely in oil of turpentine, and then formed a good cement for uniting broken glass or china. Professor Bleekrode, connected with the Dutch colonies, published, in 1857, a full account of a Surinam tree, from which excellent gutta-percha can be obtained, or at least an exudation resembling in most of its useful properties that substance. The *Bullet-tree*, or *Gutta-percha Sapota*, as this tree is now called, is very common in groups on the hilly regions of Surinam, above the alluvial plains. When quite dry, the gum weighs about 14 per cent. of the original juice, 86 per cent. having gone off in moisture. When separated by alcohol, this gutta-percha is a beautiful substance, as white as snow. When tested in various ways with heat, ether, alcohol, chloroform, benzole, oil of turpentine, sulphuric acid, nitric acid, hydrochloric acid, ammonia, caustic potash, or caustic soda, this new substance presents all the recognised qualities of true gutta-percha.

In order to extend the present amount of knowledge concerning gutta-percha, the Society of Arts, in March, 1858, appointed a committee "to direct the institution of a series of experiments on gutta-percha, and to report from time to time such observations as may appear to elucidate the nature and cause of its decay, the different qualities of the substance, modes of detecting adulteration, and any other points valuable to the manufacturer or to those who use it." The committee consisted of eleven members, comprising the consulting engineers of two of the Electric Telegraph Companies, and several scientific men. They drew up a list of thirteen questions, relating to the decay of gutta-percha, the effects of heat and weather, the effects of age or long keeping, the best mode of joining separate pieces, the insulating properties, &c.; and another list of twelve questions, relating to the growth and trade in the article—such as the kind of trees, the season for gathering, the age of the tree, the possibility of obtaining the sap without cutting down the tree, the number and nature of the kinds known in commerce, and the possibility of cultivating gutta-percha trees in localities not at present enriched by them. These printed queries were distributed largely, with a view of obtaining information from all available quarters; and the inquiries are still going on, which this proceeding suggested.

Regarded in its commercial relations, gutta-percha manufactures have not yet become largely exported. It is comparatively a new substance, and we can easily use at home all that can be procured. The manufacturers are yearly taking out patents for the application of the gum to useful purposes. The import into the United Kingdom, in 1856, was about 16,000 cwt., worth 64,000*l.*; since which year it has considerably increased.

GUTTA SERENA is that kind of blindness which arises from derangement or disease of the nerves of the eye, whether before or after their separation from the brain. The name originated in a notion, long prevalent in the schools, that all diseases are attributable to some deleterious fluid or humour circulating in the blood or diffused in the substance of the part affected. The epithet *serene* was intended to intimate the comparative freedom from pain, and the absence of any unpleasant change in the appearance of the eye, which distinguish this class of ophthalmic complaints from others equally destructive of sight. Hence Milton, whose blindness was of this kind, thus addresses Light ('Paradise Lost,' iii. 22):—

> "But thou
> Revisit'st not these eyes that roll in vain
> To find thy piercing ray, and find no dawn;
> So thick a *drop serene* hath quenched their orbs,
> Or dim suffusion veiled:"

and in the lines to Cyriack Skinner, he notices both the external peculiarity and the cause (by far the most frequent one) of his blindness, as well as the occasional suddenness of its attack:—

> "Cyriack, *this three years' day* these eyes, *though clear*
> *To outward view of blemish or of spot,*
> Bereft of light, their seeing have forgot.
> * * * * *
> * * * What supports me, dost thou ask!
> The conscience, friend, *to have lost them overplied*
> In liberty's defence, my noble task."

But the rejection of the humoral pathology has been extended to the nomenclature derived from it; and this fanciful, though still popular term, which seems to have been devised expressly for the poets, has given place in modern systems of nosology to that of *amaurosis* (ἀμαυρος, *blind*).

The most frequent seat of the complaint is the retina; the next is probably the brain itself, or that part of the optic nerve which, lying within the cranium, is in contact or communication with the brain, and partakes of its diseases. But recent observations and experiments have proved that the affection of the optic nerve may be secondary; and that the primary seat of the disease may be in certain other nerves connected with the eye, though not immediately subservient to vision. It may likewise be symptomatic of irritation in some distant organ, probably through the intervention of the same class of nerves. The temporary failure of sight during a bilious attack is of this nature: we may also here mention once for all that the affection is sometimes merely hysterical, in which case though the blindness may be total it is rarely permanent; and the same remark may be made of a kind of amaurosis which occasionally results from the irritation of worms in the intestinal canal.

The effects of remedies and some other considerations appear to lead to the conclusion that amaurosis is generally of an inflammatory nature, or dependent at least upon a congested state of the blood-vessels. It is however unquestionably sometimes the result of an opposite state, for it may be brought on by excessive or repeated losses of blood, by long-continued nursing, and by other immoderate discharges and secretions, and is sometimes the effect of mere debility.

It may be caused by simple pressure on the optic nerve, as by the growth of a tumour, or by apoplectic effusions within the head: in this case it is analogous to the paralysis of a limb. A slight stroke received unexpectedly upon the naked eye-ball may produce it, although a violent blow when the lids are firmly closed has no such consequence. In this case it is called concussion of the retina, and is analogous to concussion of the brain. It may also be the instantaneous effect of a flash of lightning. But the most frequent causes of amaurosis are exposure of the eye to too bright a light, as in watching an eclipse of the sun; or over-exertion of it in laborious study, especially at night, or in occupations such as that of the watchmaker. The Esquimaux are very subject to this complaint from the bright reflexion of their snow-fields; and have learned by experience to guard against the danger by using snow-spectacles, which are pieces of wood pierced with small circular holes, bound before their eyes, so as to shut out a part of the field of view.

We cannot enter at length into the symptoms of amaurosis, which vary of course with the seat, the cause, and the degree of injury. The chief symptoms are a more or less rapid failure of sight, by an increasing dilution of light with darkness (if the expression may be allowed), rather than by the appearance of a cloud. Moving spots, called *muscæ volitantes*, are generally seen to flit before the eyes, especially when they are closed. There is generally some degree of pain in the organ itself, and in the forehead; when the complaint arises from exhaustion, it is felt chiefly towards the back of the head. Exertion of the sight is always fatiguing and painful. The pupil is either preternaturally large or small, and obeys the stimulus of light either not at all or very sluggishly. The eyeball is sometimes too soft; in other cases unusually firm; or it may be of the natural degree of hardness. A degree of fever is occasionally present. If one eye becomes affected, the other generally follows, especially if the cause be common to both. The complaint is most usual after the middle period of life; it is frequently found to affect members of the same family, and comes on about the same age. Dissipation of all kinds, and especially habitual inebriety, predispose to it.

Confirmed amaurosis is seldom cured; but in its early stages much may be effected by careful and skilful treatment; and the means may generally be adapted with great precision to the nature of the case, by attentive consideration of its symptoms and history.

Depletion, aperient medicines, abstinence, and a darkened chamber, must of course form a part of the treatment when the case is inflammatory: but mercury, pushed if necessary to the extent of salivation, is the remedy most to be relied on; indeed, without it, the oculist would have little chance of success in any case.

When the symptoms arise from exhaustion, an opposite plan of treatment is obviously proper; but even then the moderate action of mercury is sometimes requisite. Blisters behind the ears and between the shoulders are frequently of great service in both descriptions of cases. In *sympathetic* amaurosis the attention must of course be directed in the first place to the organ which is the original seat of irritation.

This complaint not unfrequently forms a complication of cataract and of closed pupil; probably from extension of the inflammation from the parts of the eye affected in those disorders to the choroid coat or to the retina. Operations for the cure of either of those causes of blindness would be attended with no advantage in such cases, and should not be undertaken.

GUTTURALS. [ALPHABET.]

GYMNASTICS, or more properly *gymnastic* (γυμναστική, from the word γυμνός, *naked*; it being customary among the Greeks to strip themselves, wholly or in part, before engaging in bodily exercises, and thence the word has been used to denote such exercises intended to increase health and strength). The first notice of their employment is found in the second book of the 'Iliad,' where the Grecian soldiers are described as having disembarked from the ships, and playing at quoits and javelin-hurling on the beach; and again, in the twenty-third book, Achilles is represented as instituting games in honour of Patroclus, whose funeral ceremonies had just been performed, and as bestowing rewards on the victors in chariot-races, boxing, wrestling, quoit-throwing, &c. At this time these exercises seem to have been principally practised as combining amusement with the best means of obtaining bodily strength and activity; but at a later period games were dedicated to the Gods, and, being regularly established, were conducted with the greatest ceremony; honourable rewards and civil distinctions were publicly bestowed on the conquerors, the chief of whom were deemed in no slight degree exalted above their fellow-citizens. These rewards being called *athla* (ἆθλα), gave origin to the name of *athletæ* (ἀθληταὶ,) applied to those who contended for them; a designation adopted by the Romans, and from their language introduced into our own and others of modern Europe.

It was just before the time of Hippocrates, as Plato in the third book of his 'Politeia' tells us, that gymnastic was made a part of medicine, as a means of counteracting the bad effects of increasing luxury and indolence. It was gradually reduced into a complete system: public buildings called gymnasia were erected for the purpose, and superintending officers appointed by the state. The first gymnasia were built by the Lacedæmonians (Plato, Νόμοι, lib. i.), and after them by the Athenians, who had three in the immediate neighbourhood of their city: one, called Academia, where, attracted by the pleasant walks which surrounded it, and the concourse of people of all classes who daily resorted thither, Plato was in the habit of holding his conferences with his pupils; another, named Lyceum, in which Aristotle taught; and a third, called Cynosarges, which was frequented only by the lower order. Those built by the Romans were on a more magnificent scale, and from the extensive baths which were attached to them are not unfrequently called Thermæ.

The exercises practised in the gymnasia were the following:—

Dancing, which was of various kinds. In some the movements were much like those of modern tumblers; in others, balls of various sizes were thrown about in regular time from one person to another; in others, various figures and actions were gone through in imitation of battles, sieges, &c., in which the military engaged in full armour.

Wrestling.—This, like the former, was practised alike in the gymnastics of the military, of the athletæ, and of those who merely used the exercise for the sake of health. The practice seems to have been much like that of modern wrestling.

Boxing.—The use of boxing seems to have been confined to the gymnastic practices of the military and the athletæ, for neither Galen nor any other writer on medical gymnastics recommends it. It was practised naked, either with the open or clenched hands, or with brazen or stone spheres held in them (whence σφαιρομαχεῖν), or with the cæstus, which consisted of a leathern band studded with metal knobs, wound several times round the hands and wrists. A mixed exercise of boxing and wrestling (like modern boxing) was also practised under the name of *Pancratium*, but, like the two of which it was composed, it formed no part of the medical gymnastics.

Running formed a part of all gymnastic exercises.

Leaping.—There were various kinds. Besides jumping upwards and horizontally, they used to practise springing from their knees, and with heavy weights called *haltêres* (ἁλτῆρες), which they carried in their hands, or on their heads or shoulders, or even on their feet in the form of leaden shoes.

Quoits.—This game was played by all classes. The discus or quoit was a round lens-shaped piece of stone, iron, or brass, about three or four fingers thick, and nearly a foot in diameter, which was projected under-hand. [DISCUS.] There was also an exercise similar to quoit-throwing, in which the *haltêres*, or round bars of metal, somewhat contracted in the middle, and very like a modern dumb-bell, were employed.

Hurling.—In this the dart-javelin and many other missiles were thrown over-hand, the object being, as with the quoit, to hurl to or beyond a certain distance.

In addition to these exercises, which formed the regular business of the gymnasium, and which were conducted under the especial direction of the state, numerous others were practised by the Greeks and Romans, either at their public games, or as private amusements conducive to robust health, as riding, driving, swimming, rowing, climbing of ropes, swinging, mock fights of various kinds, standing erect for a lengthened period, holding the breath, shouting, &c. The use of baths, too, formed an important part of their hygiène: they were attached to all the gymnasia, and were invariably employed after exercise. [BATH.] Various officers were appointed to conduct the exercises of the gymnasium. At Athens the chief officer was called gymnasiarchus. It was his duty to superintend the whole establishment, and all the exercises; while the xystarchus superintended the more athletic only of the exercises. There was also the gymnastes, who, being skilled in medicine, was required to prescribe the kind and extent of exercise which each was to use, and under him was the pædotribos, whose place it was to wait on those exercising, to assist and instruct them, to dispense, as Galen says, the means which the gymnastes prescribed. There were also servants set apart to each set of exercises, and for anointing, for the baths, &c.

Various causes have operated to put an end to the practice of gymnastics as a part of education and as a means of maintaining health. The present mode of warfare, in which success depends so much more on the science of the commander and the knowledge of gunnery, of fortification, and other arts, than on the physical force of each combatant, has rendered the attainment of skill in each of the branches enumerated more necessary than great bodily strength or activity, and hence among the military gymnastic exercises are almost entirely superseded. The exercises of the athletæ are indeed preserved, and the art of training is probably even better understood in the present day than it was among the ancients, though the censure which the philosophers then bestowed upon such training is just as applicable at the present day. Plato ('Politeia,' lib. 3) describes the athletæ as dull, listless, and stupid, and subject to numerous diseases, cultivating nothing but a robust body, and leaving the mind in complete neglect; and Galen ('De Morborum Temporibus') speaks of them as gluttonous and heavy, sleeping long and soundly, and seldom remaining in good condition for more than five years. The same remark might be made of the present race of pugilists, wrestlers, &c., and certainly the gymnastic exercises which form part of the system of modern training present nothing in the effects which they produce, either on the mind or body, that would make their general adoption desirable.

The same cannot be said of gymnastic exercises practised under proper control, as a means of insuring a robust habit of body, and through it a vigorous intellect, or of curing certain chronic diseases. In such estimation were they held for this purpose among the ancients, that both Plato and Aristotle thought no republic could be deemed perfect in which gymnasia were neglected as part of the national establishments; nor did they estimate their value too highly. The observation of every day plainly shows how great an influence the mind and body mutually exert on each other, and if the care and cultivation of the former be a subject deserving the especial attention of the state, the proper training of the latter should undoubtedly at the same time form a part of every system of education. It is however not only necessary that exercises or gymnastics should be a part of education, but it is also necessary to provide that the gymnastics should be proper in kind and in degree, in conformity with the judicious observations of Aristotle ('Polit.,' lib. 8).

The principle on which gymnastic exercises act is evident; their immediate effect is an increase both in the size and power of the parts exercised, in consequence of an admirable law which obtains in living bodies, that (within certain limits) in proportion to the exertion which it is required to make, a part increases not only in strength and fitness, but also in size. Instances of the application of this law may be seen daily. A person is called on to engage in some new avocation, in which muscular exertion is required, and every day he is not only improved in strength and dexterity, but the muscles brought into unusual action increase rapidly in size and vigour, so as soon to surpass those of the rest of the body which have been less employed. Nor does the beneficial influence stop here. If the exertion be not carried so far as to produce excessive fatigue, all other parts of the body sympathise with the improving condition of that which is chiefly exerted; the circulation, excited from time to time by the exercise, acquires new vigour, and the blood being thrown with unusual force into all parts of the system, all the functions are carried on with increased activity; an improvement in the general health is soon manifested; and the mind (if at the same time judiciously cultivated) acquires strength, and is rendered more capable of prolonged exertion. As instances of the bad effects of a deficiency of exercise, it will be sufficient merely to allude to the condition of those who, being compelled to a sedentary occupation during the greater part of the day, neglect to occupy a part of their leisure time in some active exertion, as walking, riding, &c.

But perhaps still more injurious effects are seen in large schools of girls, and especially in those in and about the metropolis. The fashion which prescribes a long list of so-called accomplishments as essential to the education of ladies, each of which requires a portion of the day, has left little or no time for bodily exercise of any kind; and the want of attention to this necessary condition of health has produced a great part of the diseases to which young females are subject. It would be difficult to say how else it is that the proportion of girls who are affected by curvature of the spine and other deformities is so much greater than that of boys of the same age and condition in life. Dr. Forbes ('Cyclopædia of Practical Medicine') mentions the case from his own observation of a boarding-school in which "there was not one girl who had been there two years that was not more or less crooked." He adds, "scarcely a single girl that has been at a boarding-school for two or three years returns home with unimpaired health." If the condition of boys at boarding-school be compared with this statement, the conclusion is unavoidable that the exercise allowed to young females is not only insufficient as regards the time devoted to it, but of too restrained a nature. Its ill effects indeed, when they first become evident, are very generally increased by the use of various means for supporting the parts which are supposed to be weakened, and for maintaining them in a passive condition of rest; whereas the only means by which their healthful vigour can be restored is their judicious exercise. A system of proper exercises would undoubtedly be beneficial, not only to the body, but to the mind; and the loss of the time, before devoted to study, would be fully compensated by the increase of mental activity which the pupils, healthy and robust, would then bring to their studies.

Excessive exercise, on the other hand, should be carefully avoided: for though less frequent, instances are not uncommon where undue exertion has produced effects scarcely less injurious than those which result from inactivity. The existence of either class of evils is sufficient to prove that gymnastics should form a part of the education of youth, as much as "literary instruction, music, and the art of design," which, with "gymnastic," are mentioned by Aristotle ('Polit.' lib. viii.) as the four branches of instruction recognised in his day. In order that gymnastics may produce their proper results, some general system should be established in all schools, by which one sex may be preserved from the evils of deficiency, and the other from those of excess in exertion; and the beneficial influences which gymnastics exercise on the mind as well as on the body, on the understanding and moral habits as well as on the health and strength, may be secured to both.

A desire to reunite physical with mental training is, however, now becoming prevalent, and to aid in this object the suggestions which follow are made. A description of peculiar games is scarcely required, as most readers are familiar with their characteristics. The hygienic rules are equally applicable to girls as to boys up to a certain age, and the impartial adoption of them would be a benefit to subsequent generations. A more moderate use of the sports or games is necessary for girls, on account of their greater delicacy of structure and less strength. The attempts to effect the improvement contemplated should be commenced at the earliest period after birth. In this country, young children of both sexes have long been exempted from the confinement and restraint upon the locomotive organs, as also the important vital organs seated in the chest, caused by the use of swaddling or swathing bands, still in use in the French nurseries, but recourse is had at an early period for girls to supports for the back under the name of stays or corsets, the evils resulting from which have been pointed out under the latter word [Corset]. Were the same freedom of expansion of the chest secured by the disuse of this relique of barbarism, to girls as to boys, finer figures with frequent exemption from crooked spines and consumption would be the consequence. All games which can be carried on solely, or best, in the open air, are preferable to indoor amusements. This does not depend merely on the free action of the respiration, but very much on the agency of light in promoting the changes of the molecular particles of the human frame. The utility of light in promoting salutary changes in the human frame is glanced at by Dr. Andrew Combe in his excellent work, 'Physiology Applied to Health and Education,' and in other works, but it is the subject of a highly instructive chapter in Dr. Bureaud-Riofrey's 'Education Physique des Jeunes Filles,' Paris, 1835, of which we believe there is an English version.

The propriety of conducting the education of the young as far as possible in the open air is manifest. Schools in the country, when directed by competent masters, are therefore preferable to those in towns. The alternation of bodily exercise with lessons, when circumstances allow egress into the open air, is eminently conducive to bodily development and mental energy. The system of Infant Schools, when properly carried out, goes some way to ensure these conditions. The system of Kindergartens, devised by Froebel in Germany, and introduced into England by Johan and Bertha Ronge ('A Practical Guide to the English Kindergarten,' London, 1855), has the characteristic of conducting all the movements of the body in the gymnastic exercises to the rhythm of musical sounds, but though said to have proved successful in Germany, the system does not appear likely to commend itself to English habits and modes of thought. In any system of gymnastic exercises, however, for children, it is of essential importance to provide against violent straining of the muscles, as not only may permanent injury be inflicted on the healthy by excessive efforts, or unfit postures, but where gymnastics are resorted to for the cure of distorted spines or other deformities, the evil sought to be remedied is aggravated from ignorance on the part of the superintendent. (See 'Lectures on Distortions of the Spine not connected with Caries,' by Sir B. Brodie, London, 'Medical Gazette,' January, 1849.) The same objection applies to much of the clumsy, often weighty iron apparatus employed to straighten curved spines and distorted limbs. The muscles of the back, neck and arms, judiciously brought into play, are the natural and most efficient means of correcting these deformities. The games that bring the greater number of muscles into successive or harmonious play, are the best to strengthen the system during infancy and adolescence, and to maintain it in vigour and health during manhood. A few of the most appropriate may be mentioned.

Cricket.—This game combines all the conditions stated above, as essential to healthful recreation. But to insure this, moderation in the length of time the game is pursued is above all requisite; a point apt to be neglected when victory, not health, is the object. Other games, such as foot-ball, rackets, tennis, and hand-ball, or better, battledore and shuttlecock, are healthful, and the latter, besides being most suitable for females, can be played in-doors, either in winter or during wet-weather, as a substitute for out-door exercise. Another substitute for out-door exercise for females in winter, is *Dancing*. This is undoubtedly a most wholesome exercise when enjoyed in moderation, at proper hours, and in proper places. But the dancing of fashion is most pernicious; not only from the time when engaged, turning night into day, but from its being practised in hot crowded apartments, from which the partakers issue often thoroughly exhausted, inadequately clothed, and often passing through the cold damp atmosphere of early morning to encounter its depressing effects. Professional dancers, who endeavour rather to astonish than please by their extraordinary efforts, frequently become the victims of aneurism, or heart disease, and not seldom of consumption.

The game of *Golf* as played in Scotland, and occasionally by Scotchmen in England, is a healthful recreation, and is often joined in by seniors as well as juniors. The same circumstances recommend the Scotch game of *Curling*, termed also a bonspiel, in which clergymen and grave professors unite to rival each other in dexterity in projecting a polished stone, termed a curling-stone, along the ice. This turns one of the characteristics of winter into a source of health and vigour, and counteracts the evils of a sedentary life. This is a point which deserves the greatest attention on the part of literary and professional men. The indigestion of studious persons, and clerks long confined to the desk and the counting-house, arises not so much from the exhaustion of the nervous energy, as from a deficiency of *foot-exercise.* The peculiar construction of the veins of the lower extremities, which lose the valves connected with them while passing up the limbs, the moment they enter the cavity of the abdomen, and thereby become dependent on the motion of the abdominal muscles, and those of the chest concerned in respiration, for the propulsion of the blood to the liver, there to be converted into bile, explains the injurious effects resulting from too sedentary a position. Rest and foot-exercise should be made to duly alternate; and thus the bodily powers and the proper mental energy would be ensured. The mere change of posture from sitting to standing, by reading or writing for a time in the upright position, is an advantage. Besides, for either singing or reading aloud, the erect position is the best. It is invariably observed by all the greatest singers, as allowing much fuller inspirations to be taken. Whatever increases the capacity of the chest improves the health; and the greatest attention is invariably given to this point by all skilful trainers who undertake to prepare anyone for athletic feats, whether pugilism, walking, or wrestling. Unless the candidate for such honours as the ring can bestow has good wind, or can have his breath augmented by appropriate measures, success cannot be expected. Walking some distance at a moderate pace, and running up-hill for about half a mile at the top of his speed, before breakfast, form a preliminary step of prime importance. (See Captain Barclay 'On Training in Pedestrianism,' by Walter Thom, Aberdeen, 1813.) By perseverance in these means, a comparatively feeble person may be brought up to a very high condition of bodily vigour. Such extreme measures cannot be adopted by private individuals, but the principles, properly modified, can be observed. The expansion of the chest may be accomplished by easier means. On first rising in the morning, before an open window, or better still, where there is a garden, practising drawing full breaths, at first cautiously, afterwards more freely for two, three, or ultimately ten minutes, will impart a buoyancy and elasticity which will endure throughout the day. As a means of warding off consumption, few agents are more useful (See Sir Henry Holland's 'Medical Notes and Reflections,' chapter on the Exercise of the Respiration, and art. Human Longevity, in 'Edinburgh Review,' vol. 105, p. 70.) The beneficial effects of greater expansion of the chest from the kind of occupation are shown in the observations of Dr. Guy, who found that among compositors and pressmen in printing-offices, compositors were liable to consumption in the proportion of one-fourth out of a given number of patients, while pressmen were liable in the proportion of only one-fifth. (From 'Quarterly Journal of Statistical Society,' vol. vi., pp. 197, 283, quoted by Dr. Theophilus Thompson in his 'Clinical Lectures on Pulmonary Consumption,' p. 179.) The advantage of mechanical exercise after study, is well shown in the results of the trials instituted by the Mechanical Association of Andover Theological Seminary, in the United States. (See Dr. Reynolds, 'On the Necessity of Physical Culture to Literary Men, and especially Clergymen,' reprinted from the American edition in 'The Student's Cabinet of Useful Tracts,' vol. i., p. 280, Edinburgh, 1835.) A gymnasium now exists at the University of Oxford, but whether it be resorted to by those who most need it, those most apt to be "sicklied o'er with the pale cast of thought," is doubtful. The teachers of gymnastic, or as they are termed calisthenic exercises, are often incompetent to the task, and either neglect important points, or require excessive efforts from those under their direction. Few things employed to expand the chest are more hurtful than dumb-bells. Where anything beyond the habit of drawing full breaths in the open air, as mentioned above, is required, the use of the systolic and diastolic cane, invented by Mr. Tenniel, is the best that can be resorted to. It is light, expansible, and can never overstrain the muscles of those using it. Another serviceable agent in expanding the chest is to cultivate the habit of reading aloud.

> "The poet's or historian's page, by one
> Made vocal for the amusement of the rest,"

is an exercise markedly conducive to health and happiness. In the 'Quarterly Journal of Education,' October, 1834, it is justly said: "one of the accomplishments which we wish to see cultivated among females, and which is greatly neglected or wholly overlooked, is the art of reading aloud. It is a most healthy employment when used discreetly, since exercise to the lungs is as advantageous to the lungs as to all other parts of the human frame. The ability to read aloud agreeably is also a truly domestic acquirement; it will be another link in the chain which binds men to their hearths; it will amuse the young, cheer the old, and instruct the ignorant." Where circumstances prevent the use of foot-exercise, riding on horseback comes nearest in excellence; riding in a carriage is an inferior substitute. Dr. Parry in his 'Therapeutics' observes, that if it were sufficient, it would be as reasonable to give our race-horses an airing on the backs of elephants; they would then have small chance of winning in the contest. Swimming is among the most healthful of recreations when nothing forbids its use, such as great delicacy, [Bathing] tendency to fits or other spasmodic diseases, or diseased heart or lungs. Rowing, when restrained to proper limits, is useful, but exercises the upper extremities to excess and stints the lower. The Thames watermen were striking instances of unequal development of the frame. Skating, when not too prolonged, is, apart from the risk of accidents, a highly salutary recreation.

Bacon, Milton, Locke, the greatest authorities on education among the moderns, are unanimous in commending out of door exercise as constituting a portion of scholastic discipline. Milton enforces it thus: "Besides these constant exercises at home, there is another opportunity of gaining experience to be won from pleasure itself abroad; in those vernal seasons of the year, when the air is calm and pleasant, it were an injury and sullenness against Nature, not to go out and see her riches, and partake in her rejoicing between heaven and earth." Tractate, 'on Education,' § 22. But all writers with uniform consent admit,—

> "That he whom toil hath braced, or manly play,
> Has light as air each limb, each thought as clear as day."

Dr. Andrew Combe, *The Principles of Physiology applied to the preservation of Health.* Dr. Southwood Smith's *Philosophy of Health;* and *The Laws of Life, with special reference to the Physical Education of Girls*, by Elizabeth Blackwell, M.D., English ed., 1859.)

GYPSIES, a word corrupted from Egyptians, is the name given in England to a wandering race of people who are found scattered over many countries of Europe, whither they migrated from the East about the beginning of the 15th century. Pasquier, in his 'Recherches Historiques,' says that they first appeared at Paris in the character of penitents, or pilgrims, in August, 1427, in a troop of more than 100, under some chiefs who styled themselves counts, and that they represented themselves as Christians driven out of Egypt by the Mussulmans. They obtained permission to remain in the kingdom; other troops followed, and they wandered about in all directions, unmolested for many years, committing petty depredations, and their women assuming the calling of fortune-tellers. In 1560 an ordonnance of the states of Orléans enjoined all impostors and vagabonds styled "Bohemians," or "Egyptians," to quit the kingdom under pain of the galleys. The name of Bohemians, given to them by the French, may be owing to the circumstance of some of them having come to France from Bohemia, for they are mentioned as having appeared in various parts of Germany previous to their entering France; others derive the word from "Boëm," an old French word signifying a sorcerer. (Moreri, art. "Bohemiens;" and Ducange's 'Glossary,' art. "Ægyptiaci.") The Germans gave them the name of "Zigeuner," or wanderers; the Russians, "Zigani;" the Turks and Persians, "Zingarri;" the Dutch called them "Heiden," or heathens; the Danes and Swedes, "Tartars." In Italy they are called "Zingari;" in Turkey and the Levant, "Tchingenes;" in Spain they are called "Gitanos," or "Zincali;" in Hungary and Transylvania, where they are very numerous, they are called "Czigany;" but they call themselves either "Rommany," a Sanscrit word for husband or head of a family, or "Zincali," meaning the black men of Ind. The notion of their being Egyptians is probably derived from the circumstance that many of them came immediately from Egypt into Europe, but it seems proved that they are not originally from that country, their appearance, manners, and language being totally different from those of either the Copts or Fellahs.

It is now generally believed that the gypsies migrated originally from India at the time of the great Mohammedan invasion of Timur Beg; that in their own country they belonged to one of the lowest castes, which resemble them in their appearance, habits, and especially in their fondness for carrion and other unclean food. Pottinger, in his 'Travels,' saw some tribes resembling them in Beloochistan. There is a tribe near the mouths of the Indus called Tchinganes.

The language of the Gypsies seems everywhere to be mixed with the slang of the country they inhabit; but there is no doubt that it contains many Sanscrit words, and it has been found to resemble some of the dialects of India. ('Bombay Transactions,' 1820.) They have no traditions or records concerning their origin; no religion of their own, but they adopt the outward forms of the people among whom they live, whether Christians or Mussulmans. Everywhere they exhibit the same roving habits, a dislike to a fixed settlement and to the arts of husbandry, uncleanness in their food, licentiousness, ignorance and intellectual apathy, a disposition to pilfer, and to impose on the credulity of others. They seldom commit violent robbery or other heinous crimes, being fearful of punishment. Maria Theresa ordered those in her states to be instructed in agriculture, with a view to their permanent settlement; but her endeavours were not very successful. In Hungary and Transylvania, however, many of them have fixed habitations, and follow some regular trade; they wash gold from the sand of the rivers, and they work iron or copper; some are carpenters and turners, others are horse-dealers, and even keep wine-shops or public-houses. They abound in Wallachia, Moldavia, and Bessarabia, and they are found in Russia as far as Tobolsk. Grellman, in his 'Versuch über die Zigeuner,' Göttingen, 1787, conjectured that there were then between 700,000 and 800,000 in Europe, of whom 40,000 were in Spain, chiefly in the southern provinces. In England and Scotland, in both of which they were formerly numerous and troublesome, and many Acts of Parliament were passed in vain for their suppression, they have much diminished of late years, in consequence chiefly of the inclosure of land and the more effective execution of the laws against vagrants. J Hoyland published the best information that could then be procured concerning this strange race, in his 'Historical Survey of the Customs, Habits, and present State of the Gypsies; designed to develope the Origin of this Singular People, and to promote the Amelioration of their Condition,' 8vo, York, 1816. He has largely made use of the work of Grellman; but for a correct account of the peculiar manners, language, and probable descent of the race, the best authority is Mr. G. Borrow, particularly his 'Zincali; or an Account of the Gypsies of Spain.'

GYPSUM. The hydrous sulphate of lime furnishes materials which are extensively used in building operations, either for the purpose of obtaining *plaster of Paris* from the amorphous varieties; or for ornamental sculpture, when the gypsum assumes a sub-crystalline anhydrous character, known by the name of alabaster. The amorphous gypsum is raised in enormous quantities in parts of Lincolnshire and in Derbyshire, in the neighbourhood of Paris, in Provence, Tuscany, north of Spain, lower Austria, Nova Scotia, &c. The anhydrous varieties are principally obtained from the département of the Isere in France, Volterra in Tuscany, and the Guadalajara in Spain. The gypsum of the tertiary deposits of France, it may be added, contains a notable proportion of carbonate of lime, and even of soluble silica; and it is no doubt on this account that it is able to be employed in external masonry, which is not the case with the English plaster. Another peculiarity of the real plaster of Paris is that it swells with inconceivable force in setting, and therefore requires to be used with great caution.

Some artificial plasters are made, under the names of Keene's, Martin's, and Parian cements, by slacking the dehydrised sulphate of lime with solutions of borax, alum, or other salts, and then exposing it to a second calcination.

GYPSUM. [CALCIUM, *Lime, Sulphate of.*]

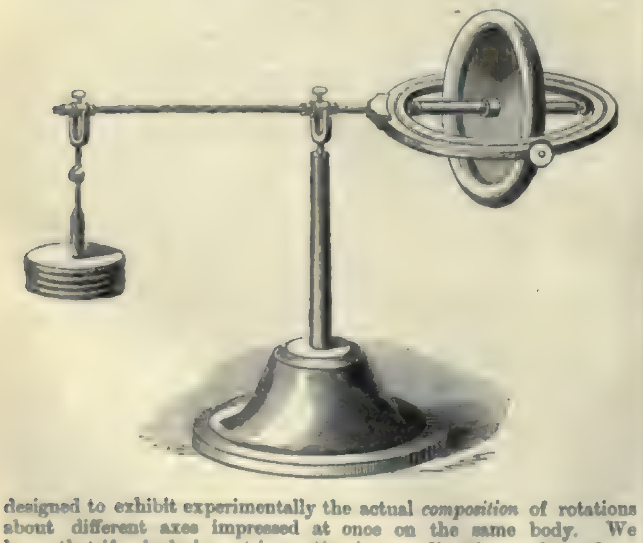
GYRATION, CENTRE OF. When a system of heavy bodies, or any system possessing weight, has a fixed axis of revolution, the centre of gyration is a point at any such distance from the axis, that the *moment of inertia* would not be altered if the whole mass were collected at that point. The moment of inertia being found by multiplying every mass by the square of its distance from the axis, the distance of the centre of gyration is found by dividing this moment of inertia by the whole mass, and extracting the square root of the quotient. As this term is now very little used, we refer to INERTIA for further information.

GYROPHORIC ACID. [LICHENS, COLOURING MATTERS OF.]

GYROSCOPE (from the Greek *γῦρος*, a circle or rotation, and *σκοπέω*, to perceive), an instrument recently suggested by M. Foucault, and improved by various modifications, and which has acquired notoriety from its supposed efficiency in rendering *visible*, by its direct dynamic effects, the diurnal *rotation* of the earth on its axis. It seems to have been originally invented in the form of *fig.* 1, by M. Fessel of Cologne, and was described in Poggendorff's 'Annalen' for September, 1853. It has since been modified and improved by Professor Plücker, and Mr. Wheatstone, and although originally invented apparently without any knowledge of Bohnenberger's apparatus, is merely a modification of it, as described in Gilbert's 'Annalen' (lx. p. 60). The essential parts of Bohnenberger's apparatus were a sphere capable of rotating about an axis whose extremities rest in opposite points of a hoop which can turn on pivots *horizontally*, within another hoop turning on pivots about a *vertical* axis.

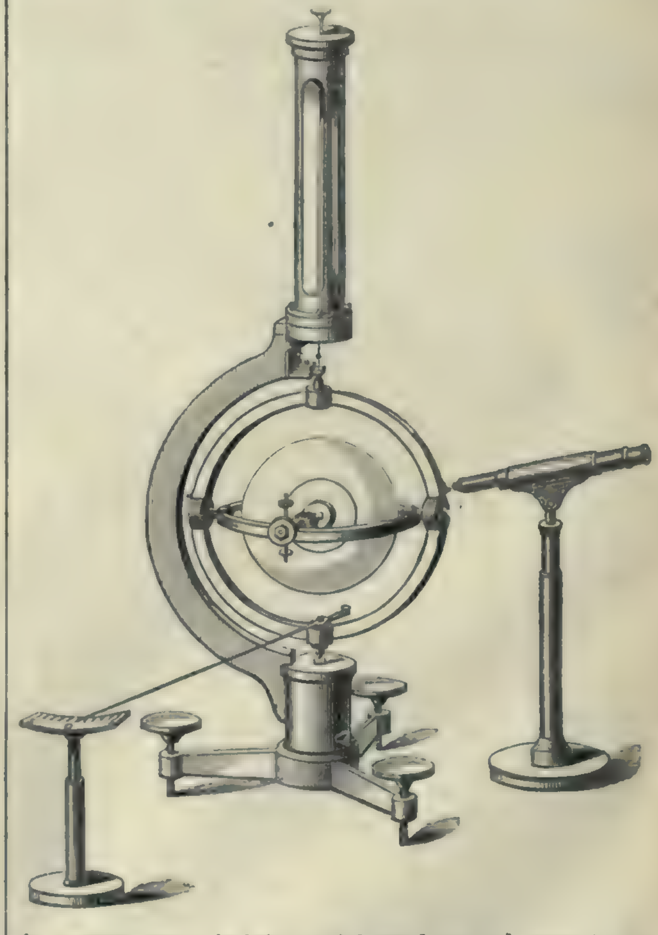
The principle on which the action of the instrument depends was discovered by Frisi about 1750, and enunciated as the principle of the "composition of Rotatory Motions;" and the instrument itself is designed to exhibit experimentally the actual *composition* of rotations about different axes impressed at once on the same body. We know that if a body be set in motion in one direction, and any force tend to make it move in another direction, it will move in neither, but in an intermediate direction. So also we have the strictly analogous case of *rotatory* motion, namely, when a body is rotating about an axis, and any force tends to make it rotate about another axis, it will not rotate about either, but about a new axis intermediate to the other two. Thus, to take a very simple, but paradoxical case (given by Professor Baden Powell, in a paper read at the Royal Institution, in March, 1854):—a wheel at one end of an axis, and a weight at the other, are suspended in equilibrio; which is, of course, unaltered, whether the wheel be at rest or in rotation; the weight is then slid so that the balance is destroyed; *now* if the wheel be set in rapid rotation, the equilibrium is restored.

Fig. 1.



The *apparent* displacement of the plane of vibration of the pendulum was first noticed by the Academicians *del Cimento*. This fact was brought to light in 1851, by Signor Antinori, director of the Museum at Florence, who found an autograph manuscript on the subject by Vincento Viviani; this note however was not published until after Foucault's discoveries, who was the first to connect this fact with the rotatory motion of the earth. M. Foucault communicated his discovery to the Academy of Sciences at Paris, on the 3rd of February, 1851. His experiment with the pendulum will be fully described under the article PENDULUM, while we shall confine ourselves here to his later invention, the gyroscope, for showing the same rotatory motion of the earth. We shall, however, first mention M. Lionville's connection between this rotatory motion and the displacement of the plane of rotation of the pendulum or disc of the gyroscope. The rotation of the earth *on its axis* has been proved by Foucault (1) by his celebrated pendulum experiment, (2) by his gyroscope. (1) Suppose a pendulum suspended over either pole of the earth, and set in oscillation. It is evident that a spectator, carried round by the rotation of the earth, would pass, first under one end of the arc of the vibrating pendulum, and then under the other, so that its plane of oscillation would appear to him to make a revolution *from east to west* in the same time as the earth revolved *from west to east.* (2) Let the pendulum be similarly suspended over the *equator*. It is evident that in this case no change of the plane of oscillation can take place, because the spectator cannot, by being carried round, approach nearer to one end of the arc of vibration than the other. (3) If the pendulum is suspended at any *intermediate latitude*. In this case, the rotation of the earth round the polar axis may be considered as the resultant of two rotations, one round an axis passing through the place of observation, and another round a perpendicular axis. But the rotation round

Fig. 2.



the latter axis, or polar axis of the place, cannot affect the apparent motions of a pendulum suspended at the equator of that axis, which is the great circle through the place of observation. The pendulum will therefore be affected only by a motion round the axis through the place, which is the case *first* investigated. And the *amount* of this motion will evidently vary as the sine of the latitude. Hence the time of *apparent* revolution of the plane of oscillation = a sidereal day × sine of latitude.

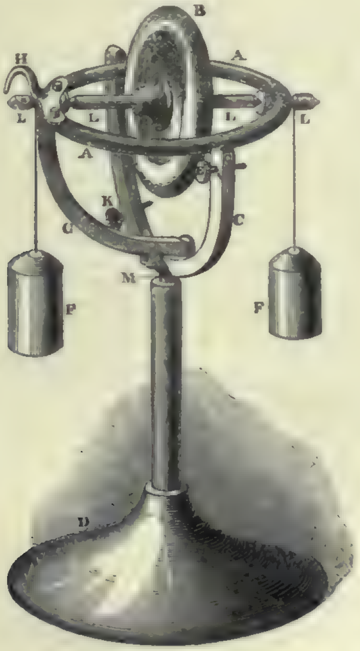
The gyroscope is an application of the well-known principle of the dynamics of a rigid body, that if a mass be set in rotation freely in space, it will, unless it be disturbed, preserve in all cases its original plane of rotation, and to effect this, will even overcome slight impediments. It will be easily seen from fig. 2, and from the description given above of the instrument itself, how the rotation of the earth is hence deduced. It was in September, 1852, that M. Foucault presented to the Academy of Sciences an account of the gyroscope. In this apparatus also there is a fixed plane below which the earth turns, and as it carries with it the spectator, causes it to appear to him as if the plane of the disc actually revolved.

The disc has the mass composing it disposed as much as possible around its edge, in order that, when put in rotation, it may revolve for a longer time than it otherwise would.

Since all the particles of this rotating disc have a tendency by virtue of *centrifugal* force to fly off at a tangent to the circumference of the disc, *in the plane* in which it is vibrating; hence, any attempt to change the direction of this plane in space will be opposed by part of the force with which, were they not restrained by the law of cohesion, each particle of the disc would fly off.

Mr. Wheatstone has described in a paper, read before the Royal Society in April, 1854, a form of the gyroscope, *fig.* 1, which we will briefly describe, as the experiments performed with it will be very easily transferred to the more perfect form, *fig.* 3. It is thus constructed: a beam is capable of moving freely round a horizontal axis, which is itself moveable round a vertical axis, so that the beam may move in any direction round a fixed point; at one end of the beam is fixed a horizontal ring which carries a heavy disc, the axis of rotation of which is in a line with the beam; at the other end is a shifting weight by means of which the equilibrium of the beam may be established or disturbed at pleasure.

Fig. 3.



If the beam be brought into equilibrium, and the disc be rapidly rotated, as by means of a string quickly unrolled from its axis, the beam will have no tendency to displace itself in any direction. But if we now disturb in any way the equilibrium, moving the weight towards the centre of the beam, and thus causing the *disc* to preponderate, then, if the disc rotates from right to left, the beam will move round the vertical axis also from right to left, and *vice versâ*. If we cause the *equipoise* to preponderate, contrary effects will take place.

The velocity of rotation of the beam round the vertical axis increases in proportion to the disturbance of the equilibrium. Notwithstanding too the increased or diminished action of gravity on the disc, its axis of rotation always preserves the same inclination to the vertical axis at which it was originally placed. When the equilibrium is disturbed while the disc is at rest, the beam being placed in any other position than the vertical, gravity acts so as to turn it round a *horizontal* axis; but when the disc is in motion, the usual effect of gravity disappears, and there is substituted for it a continued rotation round a *vertical* axis, that is, round an axis perpendicular to the plane containing the axes of the two impressed rotations.

A similar composition of forces takes place when the disc is caused to rotate while the equilibrium of the beam is preserved, by impressing on the beam a rotation round a vertical axis. When the disc rotates from right to left, the slightest pressure tending to produce rotation round the vertical axis in the same direction, causes the end of the beam carrying the disc to ascend, and a pressure in the opposite direction causes it to descend, that is, the beam is constrained to move round a horizontal axis perpendicular to the vertical plane containing the two axes of impressed rotation—a case exactly analogous to the preceding. The beam ascends and descends in like manner, after rotation has spontaneously taken place round the vertical axis in consequence of the equilibrium being disturbed, whenever this rotation is in any way accelerated or retarded. As the centre of gravity of the beam is below its point of suspension, even when equipoised, it is in perfect equilibrium only when it is horizontal, consequently, if it be elevated above or depressed below this position, it will endeavour to resume it, tending to produce in the two cases rotation in opposite directions round a horizontal axis; the rotation of the disc combined with this tendency, gives rise, as in the other cases, to continued rotation round a vertical axis; the direction being determined in a similar manner.

In all these experiments the axis of the rotating disc has been supposed to be fixed in the prolongation of the beam; but now let us suppose this axis placed at any inclination and any azimuth with respect to it, it is evident that the inclination of this axis should produce no difference in the *character*, but merely in the *intensity*, of the effects, since in any inclined position of the disc its rotation is resolvable into others, one perpendicular to the beam, and the other, which produces no effect, in a plane containing it. When the axis of the rotating disc is vertical and at right angles to the beam, no rotation on the vertical axis ought to take place in any case; but it is found that, although the beam be horizontal and in equilibrium, there is a motion round the vertical axis in opposite directions, according as one or other end of the axis of the disc is uppermost. This motion, however, is evidently due merely to the friction of the pivots dragging the beam to a corresponding motion; because whether it be accelerated or retarded no change is produced in the horizontality of the beam.

To take a few more experimental illustrations: let the system of rings carrying the disc be removed from the rest of the apparatus, and let the inner ring be allowed to move freely within the outer. Having set the disc in rotation, hold the outer ring at the end of the diameter which is in the plane in which the axis of motion of the disc is free to move; then giving to the outer ring a tendency to rotation round that diameter, in whatever position the axis is, it will fly to place itself in the fixed axis thus determined, and rotation will take place round it in the same direction; while considerable resistance is felt so long as the moveable axis is changing its position; but when once it coincides with the fixed axis, the rotation of the external ring is easily effected. So, also, a slight *alternate* motion of the outer ring, tending to give it rotation in opposite directions, will cause a continued rotation of the moveable axis; and similarly, when we try to rotate the outer ring round an axis perpendicular to its plane. In all cases, when the axis of the rotating disc is free to move in a plane, and the outer ring is constrained to rotate round a line in this plane, the moveable axis will place itself so as to coincide with that line, and so that the disc shall rotate in the same direction as the ring; if the fixed axis be in a different plane, the moveable axis will assume permanently that position in its plane which approaches nearest to the former. The moveable axis is thus *apparently* attracted towards the fixed axis, if the rotations are in the same direction, and repelled from it if they are in opposite directions.

In all these experiments the free and constrained axes of rotation are supposed to intersect, but in Fessel's apparatus they are distant from each other. In this case, the rule must be thus modified, that the free axis of rotation tends to place itself *parallel* to the constrained axis, or as nearly so as possible. By this principle all the results are easily explained. Thus, when the equilibrium of the beam is destroyed gravity tends to make it rotate round a *horizontal* axis; the axis of the disc tries to place itself *parallel* with that axis, but being unchangeably at right angles to it, the tendency to place itself there causes rotation round the *vertical* axis.

Again, fix the outer ring horizontally, and loosen the inner ring, keeping them, however, both in the same plane; then, on moving the beam round the vertical axis, the axis of the disc will fly to place itself parallel thereto. The rings being placed in the vertical plane, the same result will follow, if the beam be moved in a vertical plane, that is, round a horizontal axis of rotation.

Before describing a few more experiments with the gyroscope, we will again revert to its theoretic action, in order to explain more clearly the phenomena. We quote from a pamphlet, by Mr. Ladd, of Chancery-lane, accompanying his instrument:

"Every particle of a disc revolving on an axis has a tendency to fly therefrom, on account of centrifugal force; but diametrically opposite are the similar particles exerting the same influence on the axis. This force, influencing the axis all around, causes the rotating body to tend to preserve its plane of rotation, and with the size of the rotating body it requires a considerable increasing force to displace its axis. This fact being well understood, presents the key to the explanation of all the experiments that the instrument is capable of exhibiting.

"When the disc B is rapidly rotating, and the stand D is turned, the axis I I of the disc B will constantly point in the same direction. The friction of the vertical axis must be considered as nothing; therefore, the tendency of the disc to keep the plane of rotation is not impeded, and no effect is produced upon the same; and similar is the case when the gyroscope is taken by the stand and moved in any direction. Even an inclination of the stand D in the plane of the axis will produce no effect: that is, if the axis stand horizontally, it will continue to do so; but attempting to turn the semicircle C to the right or to the left hand, the axis of the disc will take up such a position as to coincide with the new axis which the experimenter is endeavouring to confer. In such instance two forces are simultaneously summoned into activity—the force of the hand, and the tendency of the disc to keep the plane of rotation; and the former being infinitely greater than the latter, the disc can only move in the prescribed direction. If the semicircle C and the gymbal A be connected by means of a milled headed screw K, no resistance will be felt either way. The same will be the case in one direction if the quadrant G be attached to the semicircle C; but then some other phenomena occur, because the two axes are at right angles with each other. The impossibility of the one force exerting its influence, leaves the other force free to act, as though the other were not in existence; but the force is only apparently lost, for a slight push against the semicircle will cause the instrument, as it were, to revolve round the stand on the table: that is to say, the instrument lifts a little from the table, and plays around the surface of the stand. In this manner the force that is stopped by the quadrant shows again at the bottom of the stand. If a weight F be suspended in the continuation of the axis on the screws L L, it will be unable to draw the same down, but will impart a slow horizontal motion to the spindle M. This is a beautiful and important experiment:—if the rotation of the disc be stopped, the weight will draw it down; if the horizontal motion of the semicircle be stopped, the weight will draw the disc down, however rapid may be the rotation; that is, remove the possibility that the compound effect can take place, and the one that is left at liberty will act as though the other had no existence. This remarkable fact bears analogy to some of the most important truths of the 'Mécanique Céleste.' If the rotation of the earth were stopped it would fall upon the sun, and if the possibility of the orbital revolution of the earth round the sun were stopped, it would fall upon the sun, notwithstanding its axial rotation. When the ring A with the rotating disc B is detached from the semicircle C, by lifting the screw K, and suspended by a string on the screw-head L, the disc will stand horizontally, and whilst so suspended it will revolve slowly round the suspending string as a centre of motion; the tendency of the rotating body to keep the position of its axis is so great as to resist the action of gravity on the mass, even if an extra weight be suspended on the opposite screw-head L. Another modification of the experiment is to let the arrangement rest on a hook H in the continuation of the axis in a hollow attached to the stand. If the weight be changed to the opposite side, the semicircle will turn in the opposite direction. The rotating disc freely moved in all directions by the hand, will furnish a very good proof of the resisting force which is opposed to any endeavour to change the plane of rotation; and if placed with the screw-head L on the table, it will keep itself upright like a spinning-top; and if the friction between the screw-head and the table be greater than between it and the point on which the axis turns, the ring will remain stationary. Close to the disc on the axis is a milled wheel, which may serve as a means of calculating the number of revolutions in a second. If a card be held against it, a musical tone is produced, which will rise higher with the rapidity of the rotation; if the note be taken, and the number of the teeth in the milled wheel be known, the number of the rotations can be calculated by an acoustical table."

The gyroscope then, illustrates the following principles:—

1. That inertia is a property of matter in motion, as well as of matter at rest.

2. That the power possessed by the shots projected from rifled guns of resisting the influence of gravity, is due to the *gyratory* motion given to the ball.

3. That *orbital* and *axial* motions are intimately connected, and that the speed of one may regulate that of the other.

4. That the condition of *unstable* equilibrium in which bodies remain *as if stable* (for example, a common top) is due to their rotation.

Hence the gyroscope exhibits in a marked degree the three laws of inertia.

1. That a body at rest cannot move itself.
2. That a body in motion cannot stop itself.
3. That a body in motion cannot change the plane in which it is *rotating*, any more than it can diverge from a straight line if it has only a motion of *translation*.

The mathematical explanation of the movements of the gyroscope is founded on the two following principles, given by the Rev. W. Cooke, in the 'Proceedings of the Royal Society,' for March, 1857:—

I. When a particle is made to move $\left\{\begin{matrix}\text{towards}\\ \text{from}\end{matrix}\right\}$ a plane by any applied force, but in consequence of its connection with some rigid body on the same side of the plane, loses some of its momentum in a direction perpendicular to the plane; all the momentum so lost is imparted to the rigid body, which is consequently impelled $\left\{\begin{matrix}\text{towards}\\ \text{from}\end{matrix}\right\}$ the plane.

II. When a particle is made to move $\left\{\begin{matrix}\text{towards}\\ \text{from}\end{matrix}\right\}$ a plane by any applied force, but in consequence of its connexion with some rigid body on the same side of the plane, receives an extra momentum in a direction perpendicular to the plane; all the momentum so gained is taken from the rigid body, which is consequently impelled $\left\{\begin{matrix}\text{from}\\ \text{towards}\end{matrix}\right\}$ the plane.

Let the mass of the disc of the instrument be supposed compressed into its circumference; let its radius $= r$, and let it revolve round its axis with a given uniform angular velocity $= w$.

Masses will be represented by weights; hence any accelerating force f, is due to a pressure P, acting on a mass W, so that $f = \frac{P g}{W}$, g being the accelerating force of gravity.

The centre of gravity of the disc, axle, and ring which carries the pivots of the axle, is fixed, and the whole is moveable about that centre in any manner, subject to the condition that the line of the pivots of the ring is always horizontal. Let the line of the axis be denoted by II (see *fig.* 3), and be $= a$.

Let a given force F be applied at L, in the form of a weight suspended there perpendicular to the plane A A, so that the disc may describe an angle ϕ round the lines of the pivots F in the time t, whereby any two particles m and m' in the disc describe the two arcs y and y' simultaneously. Suppose the circumference of the circle A A divided into four quadrants, and let m and m' be in the first quadrant, so that $y' > y$; then, if the disc is supposed to revolve, a particle m is carried from y to y', so as to acquire an increase of velocity from the plane A A, independently of the force F, and consequently (by the first of the above principles), all the momentum so required by the particle is lost to the disc, ring, &c.; which are thus impelled as by a force in the direction opposite to that along y or y', so as to oppose the rotation imparted by F, but to impart another round the centre of the disc, in the direction A L E in the plane of the ring, that is, in a plane perpendicular to that in which F acts. A force having the same tendency is found, by means of one or other of the above principles, in the other quadrants. Hence it may, without much difficulty, be deduced by D'Alembert's principle that

$$\phi = \frac{4 F a g}{W r^2 w^2} \sin^2 \left(\frac{w t}{2}\right)$$

This value being periodical, and ranging between the limits 0 and $\frac{4 F a g}{W r^2 w^2}$, shows that the disc makes an oscillation of less extent and duration, as the spinning of the disc is more rapid, that is, as w^2 is made greater compared with $\frac{F}{W}$; and if F be a *small* weight, as is generally used, the extent of the oscillation becomes insensible. The theoretical *maximum* of ϕ for a common instrument has been found $= 18'$.

That these oscillations do exist will be evident, if we consider that the gyroscope, with the weight attached, becomes an ordinary pendulum; and the effect of the spinning is to disturb its oscillations, and lessen their extent indefinitely, when the angular velocity of the disc is sufficiently great.

H

H is an aspirate of the guttural series, and is a faint pronunciation of the sound which in the German alphabet is denoted by *ch*. In the earliest alphabets, as the Greek and Hebrew, the symbol whence the modern character is derived [Alphabet] denoted the syllable *che* or *he*. Hence the Hebrew name was *cheth* or *heth*; and the Greek probably at first *heta*, as it was afterwards *eta*. As the guttural sound disappeared in the latter language, the letter finally denoted the simple vowel ē. On the other hand, in the Latin alphabet it was retained as the symbol of the aspirate. The English name *aitch* was probably at first *ech*, with the vowel prefixed, as in *ef*, *el*, &c. The guttural sound of *ch* is often confounded with the sibilant *ch*, as heard in *church*.

The letter *h* is liable to the following changes in different dialects or kindred languages:—

1. H is interchangeable with *c*. This is well seen in a comparison of the Latin and German languages [C, 3]. To the examples there given may be added the Latin *decem* compared with the German *zehen*, and *ducere* compared with *ziehen* (*zug*).

2. H is interchangeable with *ch*. Thus the Greek forms χειμ-ων, χειμερινος, χορτος, χαμαι, are severally connected with the Latin *hiems*, *hibernus*, *hortus*, *humi*.

3. H with *chth*. This is similar to the interchange of *p* with *pt*, as seen in the Greek nouns πολις and πτολις, πολεμος, and πτολεμος. Of the interchange between the aspirates there are examples in the Greek χθες compared with the Latin root *hes-*, seen in *heri* and *hesternus*, and perhaps the Greek χθον (nom. χθων) compared with the Latin *humo-* (nom. *humus*).

4. H is interchangeable with *g*. Examples: the German *zehe* compared with the Latin *digito-*: the German *fliehen*, *sehen*, compared with the English substantives *flight*, *sight*; and perhaps the Latin *vehemens*, the first element of which is identical with the German prefix *weg*, a derivation which will make *vehemens* equivalent to *amens* or *demens*.

5. H with *s*. Compare the Latin *sub*, *sex*, *septem*, *sus*, *salio*, with the Greek ὑπο, ἑξ, ἑπτα, ὑς, ἁλλομαι, &c. Thus the ancient Spanish town Hermandica, mentioned by Livy in his 21st book, is proved by the Greek form Helmantice to be identical with Salmantica, the ancient name of Salamanca.

6. H with *f*. Hence the Latin words *hostis*, *hostia*, says Festus, were sometimes written *fostis*, *fostia*. So, too, the French word *hors*, well known in the phrase *hors de combat*, is derived from the Latin *foris*. The Spanish language abounds in examples of this change, as in the names *Herdinando* and *Ferdinando*; so also *hermoso*, from the Latin *formoso-*; the Portuguese retains the form *formoso-*.

7. H with *w*. Many Greek words which had originally the digamma (another name for the letter *w*) at the beginning, took a mere aspirate afterwards. So in our own language the word *who* has nearly exchanged the *w* for what is sounded as an *h*; and the relative adverb *how* is no doubt derived from the relative itself. It is in this way that the Latin *homo* (*homon-*) is *uomo* in Italian and *whom* in Walachian.

8. When any consonant or consonants in the middle of words had nearly lost all sound, the letter *h* appears to have been employed as a fit representative of the vanishing sound. Hence in German *stehen* and *gehen*, for what must originally have been *standen* and *gangen*; but the *h* of the Latin *mih-i* is part of the stem, as shown by the German forms *ich* and *mich* of the same pronoun.

9. The letter *h* is often dropped altogether in pronunciation, and hence in writing also. This was perhaps the reason why the Greeks gave up the letter *h* for the little mark called the *spiritus asper*. In Latin many words are written indifferently, with or without an *h*, as *arena*, *harena*; *arundo*, *harundo*; *onustus*, *honustus*. Thus the last words show that *hon-or* and *hon-us* (*onus*), *honestus* and *honustus*, are all of the same origin, being derived from a root *hon*, denoting a *load* or *charge*, which is either an *honor* or a *burden*, according to the nature of the case. The Italians for the most part, like the inhabitants of ancient Rome, are averse to all aspirates; the people of Tuscany, on the other hand, still maintain their ancient character for the strongest pronunciation of these harsh sounds. Evidence of this is seen in the name *Leghorn*, which no doubt more accurately represents the pronunciation which prevailed on that part of the Italian coast, than *Livorno*.

HABEAS COR'PORA JURATO'RUM, a judicial writ for the purpose of enforcing the attendance of jurors, abolished by the Common Law Procedure Act, 1852. [Jury.]

HA'BEAS CORPUS is a writ at the common law, used for various purposes. When the writ of Habeas Corpus is spoken of without further explanation, it always implies the important writ which will presently be described; but it is also used for certain formal purposes in the courts of common law at Westminster for removing prisoners from one court into another, and for compelling the attendance of prisoners as witnesses, &c. But the great writ of Habeas Corpus is that which in cases of alleged illegal confinement is directed to the person who detains another; and the purport of the writ is a command to such person to produce the body of the prisoner, and to state the cause of his detention, and, further, to submit to and receive whatsoever the judge or court awarding the writ shall direct.

The old writ *de homine replegiando* was issued for the purpose of replevying a man out of custody in the same manner as chattels taken in distress may be replevied [Replevin] upon giving security to the sheriff that the man should be forthcoming to answer any charge against him. And if the prisoner was removed out of the sheriff's jurisdiction, the sheriff might make his return accordingly, and thereupon a process issued (called a *capias in withernam*) to imprison the party withholding the prisoner until he was produced. From the many exceptions, however, with which this writ was guarded, especially in causes where the crown was concerned, it was a very insufficient remedy. The decision of the judges of the King's Bench in the early part of the reign of Charles I., that they could not, upon a Habeas Corpus, bail or deliver a prisoner, though committed without any cause assigned, in cases where he was committed by the special command of the king, or by the lords of the Privy Council, caused the parliamentary inquiry which was followed by the Petition of Right, which recites this judgment, and enacts that no freeman shall be so imprisoned or detained. The court, however, and the judges, still endeavoured to uphold the prerogative of the crown; and, consequently, the statute 16 Car. I. c. 10, was extorted by the parliament, enacting that any person committed by the king himself or his Privy Council, or any members thereof, should have the writ of Habeas Corpus granted to him upon demand or motion made to the court, which should thereupon, within three court days after the return of the writ, examine and determine the legality of the commitment, and do justice in delivering, bailing, or remanding the prisoner. Still, however, new shifts and devices were made use of to prevent the due execution of this act, and eventually the statute 31 Chas. II., c. 2., was passed, which is called the Habeas Corpus Act, and is frequently spoken of as another Magna Charta. By this statute the methods of obtaining this writ are plainly pointed out, and so long as it remains in force no English subject can be long detained in prison, except in those cases where the law justifies a detainer. And lest it should be evaded by demanding unreasonable bail, it is declared by the 1 W. & M., stat. ii., c. 2, that excessive bail shall not be required.

It has been customary in times of alleged danger to suspend the Habeas Corpus Act; but these are in fact the very times when the statute is most necessary. The Habeas Corpus is the protection only of the innocent, not the defence of the guilty. A suspension of the Habeas Corpus Act is effected by an act of parliament authorising the crown, for a limited period, to imprison suspected persons without giving any reason for so doing. But it has been customary to pass acts of indemnity subsequently, for the protection of those who have acted under the suspension. An instance of the one is afforded by the 57 Geo. III. c. 3, and of the other by the 58 Geo. III. c. 6. (Blackst., 'Comm.,' Mr. Kerr's ed., vol. iii.)

The statute 31 Chas. II. has been re-enacted or adopted, if not in terms yet in substance, in most of the American states. The New York statutes formerly provided for relief under the writ *de homine replegiando*, in favour of fugitives from service in any other state; but this provision has been held to be contrary to the constitution and laws of the United States, and void in respect to slaves being fugitives from states where slavery is lawful. (Kent's 'Com.')

HABE'RE FA'CIAS POSSESSIO'NEM, a judicial writ directed to the sheriff, commanding him to put the person who has recovered a chattel or possessory interest in lands into actual possession. It corresponds to the *Habere facias seisinam*; but now that the possession alone is recovered in ejectment, this writ is the one most in use. [Execution.]

HABE'RE FA'CIAS SEISI'NAM, a judicial writ directed to the sheriff, commanding him to put the person who has recovered a freehold interest in lands into actual possession. In the execution of this writ, as well as of the writ of *Habere facias possessionem*, the sheriff may justify breaking open doors if the possession be not quietly delivered. The execution is effected by the delivery of a twig, or a clod, &c., if land; or by the delivery of the key of the door, &c., if a house is the subject matter of which the sheriff is directed to put the recoveror in possession,—all other persons being first removed from the premises. But if it be the presentation to a benefice which is recovered, the execution is by writ *de clerico admittendo*, directed, not to the sheriff, but to the bishop or archbishop, directing him to admit and institute the clerk of the recoveror. [Execution.]

HACKNEY COACH. [Stage Carriage.]

HÆMATE'MESIS (from αἶμα, blood, and ἐμέω, to vomit), a bleeding from or into the stomach. [Hæmorrhage.]

HÆMATO'CELE (from αἶμα, blood, and κήλη, a tumour), an effusion of blood into the scrotum.

HÆMATO′XYLON CAMPECHIA′NUM (Logwood), a tree native of Campeachy, but cultivated also in both the West and East Indies. The finest wood is the produce of the former place. The bark and alburnum being removed, there is within a dark red coarse-fibred duramen, having a violet-like odour, and a taste at first sweetish, afterwards astringent. It dyes the saliva violet-coloured, and produces a similar change on many of the other secretions. Specific gravity, 1·057. Ten pounds of wood yield 16–18 ounces of extract. Its chief constituents are volatile oil, resinous or fatty matter, a principle termed *hæmatoxyline*, which is occasionally found in the wood in the form of crystals, and a brown matter containing tannin.

Logwood acts as a mild astringent in hæmorrhages or increased secretions; and in some forms of diarrhœa it often effects a cure where more powerful astringents fail. (See Abercrombie on 'Diseases of the Stomach, &c.') It may be exhibited in the form of infusion or of extract: the former is preferable. It is accused of causing phlebitis, or inflammation of the veins, in some cases where it had checked the diarrhœa; but this is very rarely met with. Logwood is also used extensively in the arts, especially for dyeing. It gives the peculiar colour to the paper in which sugar-loaves are generally wrapped. It forms the basis of red ink, when Brasil wood is not used.

HÆMATU′RIA (from *αἷμα*, blood, and *οὖρον*, urine), voiding of bloody urine. [Hæmorrhage; Kidneys, Diseases of.]

HÆMO′PTYSIS (from *αἷμα*, blood, and *πτύω*, to spit), a spitting or coughing of blood. [Hæmorrhage; Lungs, Diseases of; Phthisis Pulmonalis.]

HÆMORRHAGE (from *αἷμα*, blood, and *ῥήγνυμι*, to break). The most common cause of hæmorrhage is external violence, by which the vessels of a part are divided, and the blood escapes from their cavities. When an artery of some calibre is wounded, a bright scarlet stream of blood is propelled to a distance proportioned to the size of the vessel, in a current continuous, yet increased in force at intervals corresponding with the pulsations of the heart. This is called a jetting stream. If a vein of some size be divided, a stream of dark crimson blood is projected in a perfectly continuous and equable current, and with less force than from an artery of the same calibre, in consequence of the loss of power which the blood sustains in its passage through the minute capillary vessels. In wounds in which no vessel of more than a line in diameter has been divided, the blood flows in a constant more or less rapid oozing, but is not projected to any distance from the body; and when it issues from both kinds of vessels at once, and in equal quantities, its colour is intermediate between those peculiar to each of them. The same mixture of the two kinds of blood may sometimes, when a number of small vessels of both kinds, and a large one of either kind, are simultaneously divided, make it doubtful, from the colour alone, to which kind it belongs; and the distinction becomes still more difficult if the arterial blood be long detained in the tissues, for then it assumes a venous colour.

When a large artery, as one of the main trunks of the limbs or head, is divided, the blood rushes forth with such impetuosity that life is often destroyed almost instantaneously. The quantity of blood lost however, and the rapidity with which death ensues, will depend in some measure on the freedom of exit which the blood finds after issuing from the wounded vessel, as well as on the mode in which it is wounded. If there be a free external aperture, no obstacle is presented to its flow, and death speedily follows; if, on the contrary, the aperture be small, as in a punctured wound, the blood can escape but slowly, and is liable to coagulate in the passage, so as partially to block it up and render it still more narrow. If again the artery be completely divided, its extremities will retract into the tissues around, and be thus partly covered, so that the hæmorrhage will be retarded. If it be cut longitudinally, the blood will flow much less rapidly than if the wound be transverse, because the aperture will gape much less widely. If, lastly, the wound be not cleanly made, if the edges be rough and torn, as by a gun-shot, no blood at all will flow, at least for some time. None of these circumstances, however, is likely to do more than retard the fatal consequence of a wound of a large artery, unless immediate assistance be given.

When an arterial branch of the second magnitude, as one of the primary divisions of the main trunks in the leg or fore-arm, is wounded, the flow of blood is at first profuse, and a large quantity is soon lost; but after a time the patient faints from extreme exhaustion, and then the heart ceasing to act the blood no longer flows, but begins to coagulate both within and around the vessel, whose extremities contract, and further loss may thus be prevented. More frequently, however, as soon as the patient recovers from his exhaustion, and the heart regains some of its power, the slight obstacles formed during the fainting are forced away, and the hæmorrhage recommences and continues till the patient is again exhausted. Thus by a succession of hæmorrhages and of temporary staunchings, he may at last be destroyed by extreme debility. From arteries of smaller size, as those about the fingers, &c., the blood flows at first in a rapid little stream, but after a few minutes, if they are exposed to the cold air, they retract; their orifices contract and close, and the bleeding altogether ceases, without much danger of returning.

Hæmorrhage from wounded veins is of less importance. It is much more slow, for the blood is prevented by the valves from flowing from that part of the vein which is between the heart and the orifice, and in the part which is beyond the orifice it has only the force of that in the smaller arteries. Hence it is seldom immediately fatal, and when the patient becomes faint the edges of the vessel fall together, instead of remaining open as those of arteries. Thus a coagulum forms within and around them, and, except from the largest trunks, prevents any further flow. Other cases in which bleeding takes place from large vessels are those in which they are burst by sudden efforts, as sometimes happens in the aorta, especially when it or the heart is diseased; those in which the walls of an aneurism or otherwise diseased artery or vein burst or ulcerate; those in which ulceration, whether in internal or external organs, spreads from surrounding parts, and at last (though they always resist for a long time) invades the walls of arteries and veins. The bleeding so common from ulcerated surfaces, and from various vascular morbid growths, probably depends on rupture of the very delicate vessels which they contain; and the same delicacy of the walls of its vessels, with their great liability to disease in advanced life, may be assigned for many cases of hæmorrhage in the more vascular parts of the brain producing apoplexy.

But bleeding to a great extent may take place without visible rupture of any vessel. This form of hæmorrhage, which may take place in various parts of the body, is that popularly supposed to arise from the "bursting of a blood-vessel;" but in the large majority of cases where blood is poured forth in the interior of the body, the most careful examination can discover no aperture through which it had flowed. It is therefore called hæmorrhage by exhalation, from the idea that the vessels which in health are traversed only by the fluids of the exhalations or secretions, now permit the passage of the blood. The only instances in which the blood has been seen flowing in these cases are those extremely rare ones of hæmorrhage from the skin of the face, hands, feet, &c. In these the surface is covered by a dew of blood; if this be wiped away no unnatural appearance is perceptible, but the blood soon exudes again. From this the process would appear to be very similar to that of menstruation. When internal organs from which hæmorrhage has taken place are examined after death, they are sometimes found loaded with blood, but at others quite pale, their vessels having been completely emptied; when pressed, small clots of blood like grains of sand sometimes ooze out on the surface, as if proceeding from the orifices of secreting ducts. From these and other circumstances it is probable that the blood does pass through the vessels which naturally are permeated by the secretions, though the minute details of neither process are yet wholly explicable. It cannot however be certainly affirmed that the minute blood-vessels are not ruptured, for neither the apertures nor the cicatrices in them could be in any way visible.

The circumstances under which these hæmorrhages take place are various. In some cases they arise from distension of the vessels in consequence of some local excitement, either with or without increased activity of the circulation generally; and in these the flow of blood is preceded by a sensation of fullness and throbbing in the part, which, if visible, appears red and swollen. Such are those which take place in bronchitis, producing some rare cases of hæmoptysis; in dysentery and acute inflammation of the intestines; from the membrane of the nose, producing the epistaxis so common in young persons in robust health; in the brain, producing some forms of apoplexy, especially those connected with hypertrophy of the heart; and occasionally in the acute inflammations of nearly all the tissues. In other cases the main cause of the hæmorrhage is the existence of some obstacle to the free passage of the blood through the vessels. Such are those very frequent cases in which hæmoptysis, or spitting of blood, takes place in consumption, where the blood is obstructed in its passage through the pulmonary arteries by the masses of tuberculous matter deposited around them; those of hæmatemesis, or vomiting of blood, which arise from obstruction of the splenic or portal vein, by coagula, or by disease of the liver or other adjacent organs, and the consequent congestion of the vessels of the stomach; many of those which occur from the stomach, uterus, and other organs, in the early stages of various structural diseases; those which depend on disease of the heart, producing obstruction in the large vessels, and which may take place in the brain, lungs, and various other organs; and those arising from obstacles in the veins, as in hanging, or even from the influence of gravitation.

But a simply mechanical distension of the vessels, whether from an increased afflux of blood into them, or a retarded removal of it from them, cannot explain all the phenomena of these spontaneous hæmorrhages. In many cases a peculiar condition of the vessels, or of the blood itself, must be assumed, and is indeed nearly proved. To these must be referred many cases of what is called idiopathic hæmorrhage, as in some instances of hæmatemesis, hæmaturia, &c. In some persons, indeed, there appears to be a peculiar disposition to bleeding, a hæmorrhage diathesis. Mr. Abernethy ('Surgical Lectures') used to speak of a bleeding family, in all of whom it was extremely difficult to staunch the blood from even the slightest wound; and among other similar cases are not a few in which fatal hæmorrhage has followed the extraction of a tooth, or, in children, the application of leeches. Every surgeon, also, must have observed that in the same operations in different persons the number of vessels requiring to be tied varies greatly; in some amputations, for example, it is not necessary to secure more than the main artery, while in others eight or more must be tied, and this not admitting of any explanation from local differences

Many other circumstances might be adduced to show that there are conditions of the smaller vessels in which they may not only more easily permit hæmorrhages, but are less capable of effecting those changes which are necessary for arresting them, and on these conditions the majority of the hæmorrhages termed passive must be supposed to depend. Such are especially those from the nose, rectum, and other organs, which occur in persons of weak lax habit, and which may be distinguished from the first class we have noticed rather by the general appearance of the patient than by any local circumstances.

Lastly, there are cases in which the hæmorrhages that take place, often coincidently from several organs, may be presumed to depend on alterations of the blood itself. Such are those that occur in scurvy, in which the blood, when drawn from a vein, does not separate, as in health, into a firm coagulum and a clear serum, but settles into a loose, livid, or dark jelly-like mass, and rapidly putrefies. Such, too, are probably the petechial and other effusions of blood in fever.

Hæmorrhages by exhalation may take place habitually or constitutionally, without injuring the health; most commonly the blood flows from the nose or rectum, more rarely from the lungs or stomach, or even from the skin. They are sometimes periodical; and when occurring in men, have seemed to favour the idea of a periodic action of the system in the male sex as in the female, and the more so as the menstrual evacuation, when suppressed in the latter, is not unfrequently compensated for by hæmorrhage from some other organ. Most of the cases of spontaneous bleeding from the skin are of this class; and in other instances the blood has flowed at regular periods from the gums, the breasts, umbilicus, axillæ, or kidneys, but most frequently from the stomach or lungs. Similar vicarious hæmorrhages occur in men when an habitual discharge from any organ has been suppressed, or when an old ulcer has been suddenly healed.

Of the means of arresting Hæmorrhages.—When an artery is wounded, unless death rapidly follow, a natural process takes place by which further bleeding may be prevented. If completely divided, both extremities retract into the sheath of cellular tissue in which they lie, so that a considerable interval is produced between them, bounded by loose and irregular walls, into which the blood as it flows infiltrates, and, coagulating, tends to fill it up and obstruct the vessel. The open mouths of the artery also contract, and gradually, but at last completely close, either at or just above their extremities. As the stream of blood is thus checked by the narrowing and closing of its canal, at the same time that, by the faintness induced by the previous loss, the action of the heart is weakened and the whole circulation retarded, it begins to coagulate within the vessel itself, till its tube is nearly filled by a clot adhering loosely to its walls. Further changes then ensue; the divided vessel and the parts around become inflamed; coagulating lymph is effused from the edges of the wound into the artery itself and over its extremities, forming a firmer plug than the blood alone had. In process of time this lymph becomes organised, vessels enter it from the parts around, and it becomes firmly and permanently united to them and the vessel, till at length its tube is rendered impervious from the point of division up to the first branch given off from it, and is at last converted into a solid cord, closely connected with the substance of the cicatrix around it. If the artery be only partially divided, the same effects follow; though, if the cut be extensive transversely, with less certainty, because retraction cannot take place, and the internal coagulum, if formed, is washed away by the stream which still partly passes along the vessel. The natural cessation of hæmorrhages from veins is effected in the same manner, but far more easily; for the valves prevent any bleeding from the part nearest to the heart, and both orifices, instead of gaping open, fall together, and soon become adherent.

But in the human subject it is only in the very small arteries that the hæmorrhage can be confidently expected to terminate thus naturally, and hence various artificial means of checking bleeding from the larger ones have been invented. The simplest of these is pressure: if the finger be placed with moderate firmness over the mouth of a small bleeding vessel for a minute or two, on removing it the orifice will be found closed, and no more blood will flow. Pressure is also especially useful when a number of small arteries are bleeding together, with a constant oozing rather than a rapid flow of blood: in such cases, when the edges of the wound are brought together, a compress should be laid on, and bandaged firmly and steadily over them. The same means, or a tourniquet applied a short distance above the wound, so as to compress the trunk of the artery, may be useful by lessening the force and volume of the current, and thus permitting the natural processes to take place undisturbed. But if these means be insufficient, the artery must be tied; if it be completely divided, ligatures must be placed on both extremities; and if only partially cut, then on both sides of the opening—for, from the numerous communications of the arteries, when the main current is checked, another in a retrograde direction is always established into the part beyond the ligature. The operation of the ligature is not merely to prevent mechanically the flow of blood from the opened vessel. When a fine cord is drawn tightly round an artery, something is felt to give way under it, and, on removing it and opening the artery, its inner and middle membranous coats are found cleanly cut through as with a knife, while the outer coat remains. When the ligature is left on, it embraces this outer coat loosely, and thus rendering the canal impervious, completely prevents further bleeding. The blood thus becoming stagnant, coagulates in the lower part of the vessel and adheres to its walls; these at the same time inflame, coagulating lymph is effused from their cut edges, and becoming organised, at last, as in the natural process, completely fills up the canal of the vessel, while the part constricted by the ligature ulcerates and gives way, permitting the cord to be safely drawn away at the end of from six to sixteen days.

Previous to the general use of the ligature, introduced by Ambrose Paré in the 16th century, numberless means for checking hæmorrhages, then so frequently fatal, were resorted to by surgeons, under the names of styptics, astringents, &c. They were in the habit of applying hot irons to the stumps of amputated limbs to stop the bleeding, which it is probable the eschar thus formed would generally effect. At present however the use of the actual cautery is nearly abolished in this country; it can only be justifiable in the few cases where, from peculiarity of situation, the vessel can neither be tied nor compressed, and for such cases it is certainly the most effectual styptic known. Cold air or ice is nearly as useful, and far oftener applicable: it is quite sufficient in all common cases where only small vessels are divided. In the very few cases where any astringents are required, as in some of external bleeding from diseased surfaces or from tumours, the best are solutions of sulphate of copper and of alum. Another class of remedies that may be usefully employed are those which act mechanically—as sponge, agaric, lint, and other light very porous bodies, which placed over a small bleeding orifice will soon completely obstruct it by favouring the coagulation of the blood.

Such are the principal modes of treatment applicable in cases of external or surgical hæmorrhage in which vessels are divided by external injury, and are within reach of the eye or fingers. In internal hæmorrhages however it is obvious that mechanical means can rarely be employed. From the varied nature of the cases from which they arise it is evident that different means may be required in the several kinds of cases. In those so closely related to inflammation, in which there is accumulation of blood from local or general excitement, the hæmorrhage is itself a naturally curative means of its cause, and need not be checked unless it implicates some important organ, as the brain, and then the most advisable means of arresting it is to bleed from the arm. So, too, in cases of habitual or vicarious hæmorrhages, if not dangerous or very inconvenient from locality, it will seldom be advisable to check them, for they are generally outlets by which a plethoric condition that would else be highly injurious is cured; at any rate they should be arrested gradually and cautiously. Where external means are applicable none are so useful as cold, or, as a last resource, pressure; as by plugs put in the nostrils, &c. Where a mechanical obstacle to the passage of the blood exists, medicine can often do nothing for the permanent cure of the hæmorrhage that it produces. For the time, the most effectual means are cool air, cold water or ice applied as near as convenient to the seat of bleeding, iced drinks, perfect quietude, and the avoidance of all stimuli; the body should be placed in that position in which blood may gravitate from the affected part, and if there be any indication of plethora or accelerated circulation blood should be drawn from the arm to an amount to be determined by the circumstances of the case. In many cases great benefit results from exciting the vessels, of and near the part, to a copious secretion of the usual fluids, as in some cases of hæmatemesis by administering purgatives. If astringent remedies be deemed advisable, and in many cases they are highly useful, the acetate of lead will generally be preferable, and next to it the different vegetable compounds of gallic acid. [ASTRINGENTS.] The treatment of the peculiar class of hæmorrhages from alteration of the blood is considered under FEVER, &c. Bleeding from the nose is treated under EPISTAXIS. (J. F. D. Jones, *On Hæmorrhage and the Ligature*; T. Watson, *Cyclopædia of Medicine*, art. 'Hæmorrhage.')

HÆMORRHOIDS (from *αἷμα* blood, and *ῥέω*, to flow), varicose tumours of the veins of the rectum. [ANUS, DISEASES OF THE.]

HÆRETICO COMBURENDO, WRIT DE. [HERESY.]

HAGUE, ALLIANCE OF THE. [TREATIES, CHRONOLOGICAL TABLE OF.]

HAIL, HAILSTONES, HAILSTORMS. The conversion of the aqueous vapour which is an essential constituent of the atmosphere, by the depression of its temperature, either successively into water and ice, or immediately into the latter without the sensible intervention of the former state; and whether in the atmosphere itself, or on the ground, or against the surfaces of bodies resting upon it or extended into the air, presents several subjects for philosophical investigation, all of them having important relations to the welfare of man and of the various beings of organic nature he associates around him, as well as to the operations of human life. Water in the solid state is produced from the atmosphere in several ways, and in different forms. When a portion of the vapour in the air at certain elevations freezes, by the sudden reduction in temperature of its entire mass, it becomes converted into innumerable separate congeries of minute perfect crystals of ice, which are called flakes of snow; when that in contact with solid bodies forming part of the surface of the earth, or immersed in the atmosphere, becomes sufficiently lowered in temperature by their loss of heat by radiation, hoar-frost appears; and under other physical circumstances we shall now proceed to describe, another and distinct form of atmospheric ice is produced, termed HAIL.

Sir John Herschel has stated his views of the philosophy of this subject in the following terms: after relating the observation, during a balloon ascent, of the temperature of 46° Fahr. at the height of 12,000 feet, and that of 22° only, or 24° colder, at the same elevation in the descent, a heavy fall of snow being then and there in progress, he says:—"It is evident that this arose from the condensation of vapour at that level, and that, from the intrusion of some current, a mass of intensely cold air had been introduced, which, finding vapour near saturation, converted it into snow. It is equally evident," he continues, "that had the latter condition prevailed, not at the level in question, but at a somewhat higher, where the condensation might have been into *rain* very near the freezing point, the drops in descending would have been frozen solid, and fallen as *hail*. It might have been so equally, had the precipitation been so copious as to allow the coalescence of a great number of minute particles in a nascent state into drops frozen together instanter, since there is good reason to believe that the solid form is never assumed without transition through the liquid, however momentary.[*] The generation of hail seems always to depend on some such very sudden introduction of an extremely cold current of air into the bosom of a quiescent, nearly saturated mass. Hailstorms are always purely local phenomena, and never last long. They often mark their course by linear tracks of devastation, of great length and very small breadth. In the hailstorm of July 13, 1788, which passed across France from south to north, two such tracks were marked, of 175 and 200 leagues in length respectively, parallel to each other, the one four leagues broad, the other two, and separated by a tract five leagues in breadth in which only rain fell. A similar character is very common, though not to such an extent. Such linear hailstorms are always attended with violent wind, sudden depression of the barometer, indicating a great commotion in the air, and probable mingling of saturated masses of very different temperature. . . . . . Great hailstorms are often preceded by a loud clattering and clashing sound, indicating the hurtling together of masses of ice in the air. The recent experiments of [Professor Faraday and] Professor Tyndall on the re-uniting of broken ice by 'regelation,' or a sort of welding, fully explain the formation, under such circumstances, of large masses of ice of irregular forms in this aërial conflict." (*Meteorology*, 'Encyc. Brit.' vol. xiv.)

The following account, extracted from the celebrated 'Climate of London,' by Mr. Luke Howard, F.R.S., of a hailstorm as observed at Plaistow, in the county of Essex, near the metropolis (the scene of his first series of meteorological observations), on the 19th of April, 1809, affords an instructive example of the local phenomena of such storms:—"The day had been sultry, like some preceding ones, and overcast with clouds, which during the afternoon gave evident demonstrations of an approaching discharge of electricity. Large and deep *cumulo-strati* were ranged side by side, mingled with the *cirro-cumulus* and *cirro-stratus*, the whole having that peculiar, almost indescribable character, which these charged conductors assume when wrought up to the highest state of electric *tension*. About five in the afternoon, being at the laboratory, and perceiving a continued roll of thunder, with vivid lightning approaching from the south, and the appearance of a heavy shower in that quarter, I anticipated a storm of no common violence. We were proceeding to take measures for the safety of some glass utensils, when in an instant there opened upon us a volley of hail of such tremendous force, as in ten, or at most fifteen minutes, demolished most part of the skylights and south windows in the neighbourhood. These *icy bullets*, some of them a full inch in diameter, were discharged almost horizontally from a cloud to the windward, and in such quantity as to be drifted in large masses under the walls. Whether borne by the impetuous blast that came with them, or carrying the air thus before them, I could not determine, but such was the velocity of their motion that in many instances a clear round hole was left in the glass they pierced; and one large pane (which I saw) had two such perforations distinctly formed, the glass otherwise whole. The water in the river, lashed by the hail and raised by the wind, resembled a cauldron boiling violently, rather than waves with breakers. The electrical discharges were incessant, approaching with the cloud and passing off with it: . . . . This sudden irruption over, it rained for a while moderately. The wind was at first E., then S. during the hail, then W., then E., then W. again. About seven, the clouds all at once put off their stormy character . . . . . The remainder of the evening was calm and pleasant. A person who was on the road *from London to Bow* (probably not two miles off) during the storm, informed me that he experienced nothing but continued thunder and lightning, and *very heavy rain*, the latter appearing luminous on the ground on each side of him, which it often does in heavy storms. It was evident from other circumstances that the hail was bounded in a western direction by the village of Bow, and it reached eastward from thence only about three miles. Its course appears to have been from S. to N., over Blackheath, Bromley, Plaistow, West Ham, and so up the country between the rivers Lea and Roding." The amount of damage occasioned by the hail in this case is mentioned in the sequel of this article.

Many other accounts of hailstorms, and remarkable falls of hail, and of hailstones of remarkable character, at various periods, in England and other countries, are distributed through the 'Climate of London.'

In the article 'Hail,' in Brande's 'Dictionary of Literature, Science, and Art,' it is stated that "Hail usually precedes storms of rain, sometimes accompanies, but never or very rarely follows them, especially if the rain is of any duration. The time of its continuance is always very short, generally only a few minutes, and very seldom so long as a quarter of an hour." The writer of the article referred to further remarks, that "the clouds from which hail is precipitated appear to be of very considerable extent and depth, inasmuch as they produce a great obscurity. It has been remarked," he adds, "that they have a peculiar gray or reddish colour, and that their lower surfaces present enormous protuberances, while their edges exhibit deep and numerous indentations." Other characters of these clouds have just been noticed.

Single hailstones have generally a crystalline structure, radiating from a centre if large, forming spherical, oval, or rounded masses, often marked out (on making a section,) into concentric layers, like the rings in the section of the trunk or branch of a tree. The form is often conical, with a rounded base, when they appear to consist of fibres meeting at the apex, but there is reason to believe that these are portions of spheroidal concentric-laminar concretions. They fall from the size of small peas, or much less, to that of an egg, an orange, or a man's head, and weighing from a few grains up to fourteen pounds and upwards. Very frequently hail falls of which each separate stone is, or originally was, a regular tetrahedral crystal of ice, generally with convex faces, apparently owing to the tendency of crystals belonging to the monometric system of crystallisation to which ice in part belongs, to assume curved forms. Often, these have an obvious concentric-laminar structure, and they are often degraded into a conical form by their solid angles and edges becoming rounded by partial melting during their fall. Some large hailstones of concentric structure have a tetrahedral nucleus, the polyhedral having been gradually converted during accretion into a spheroidal solid. As indicated above, the concentric-laminar is also a fibrous structure in hail as in hæmatite and other terrestrial minerals. In the 'British Mineralogy' of the late eminent naturalist-draughtsman James Sowerby, a work through which are scattered many valuable facts, is an excellent plate of a mass of tetrahedral hailstones, with separate figures of the constituent crystals and their structure. Sir J. Herschel has cited from Dr. Thomson's 'Introduction to Meteorology' a remarkable example of large hailstones of a radiated structure, but such as to evince that the particular stone examined had been formed in passing through two distinct regions of condensation in the air. He also cites from Dr. Buist the observation that in India the hailstones are from five to twenty times larger than the average magnitude of those in England, often weighing from six ounces to a pound, being seldom less than walnuts in size, often as large as oranges and pumpkins. The storms in which they are produced are almost always accompanied by violent wind and rain, thunder and lightning, and are frequent in the delta of the Ganges, especially in the low country within fifty miles of the Bay of Bengal.

Sir J. Herschel, also, after alluding, as above, to the effect of regelation in producing masses of ice in the air by the consolidation of aggregated hailstones, remarks, that "such are recorded to have fallen of almost fabulous magnitude," of which, but with great caution, he proceeds to recite several examples. The effect of the process of regelation (or to adopt the recent correction of Professor James Thomson, of that of *melting and regelation*) in converting congeries of hailstones into masses of ice is indubitable, but we are in need of sufficiently authenticated statements of the actual fall of such masses. We appear not to have any account of such a phenomenon by a qualified observer, and it is to be believed that in many instances a mass of ice really produced on the ground by the consolidation of hailstones which have fallen within a small area and heaped one upon another, has been supposed to have actually fallen ready formed. The following case from Dr. J. D. Hooker's 'Himalayan Journals' will illustrate the view now taken. On the 20th of March, 1849, at noon, a violent hailstorm coming from the south-west, occurred in the Terai, or damp forest-tree region, intervening between the plains of India and the Himalaya mountains, in this locality the Sikkim Himalaya. The hail was of "a strange form, the stones being sections [sectors or segments] of hollow spheres, half an inch across and upwards, formed of cones with truncated apices and convex bases," aggregated with their bases outwards. The fall of the large masses was followed by a shower of the separate conical pieces, and that by heavy rain. "On the mountains this storm was most severe: the stones lay at Dorjiling [of which place the mean temperature in March is 45° Fahr.] for seven days, congealed into masses of ice several feet long and a foot thick, in sheltered places. At Purneah, fifty miles south, stones one and two inches across fell, probably as whole spheres." Mr. Howard quotes a notice of a hailstone fallen in Hungary in 1803, which is stated to have exceeded the strength of eight men to lift it. This, he remarks, recognising (as far back as 1833) the *fact* as well as the principle of what is now

---

[* On this subject see a paper by Mr. Brayley, 'On the probable existence of but two States of Aggregation in Ponderable Matter,' Annals of Philosophy, New Series (for September, 1826,) vol. xii. pp. 195–200.]

termed regelation, was doubtless "what is called 'an ice-board' formed by hail agglutinated in a hollow, by partial fusion on the surface, the whole freezing again by the intense cold within." The largest hailstones are stated to be of very rugged and irregular form, resembling portions of a great sheet of ice broken into pieces. An American observer, the Rev. D. A. Clark, cited in the 'Climate of London,' saw in the heat of summer, hailstones about one-fourth or three-eighths of an inch thick, and of sufficient diameter to hide a shilling, almost every one of which was perforated in the middle, as if it had been held between the fingers till thus melted. When the perforation was not complete, there was in every case a tendency to it. These were probably of the concentric spheroidal laminar structure, in which the central portions were incomplete. Mr. Howard has himself described a freezing shower which fell at Plaistow on the 19th of January, 1808, and which glazed the windows, and encrusted the walls, and encased the trees, the garments of passengers, and the plumage of birds. A portion being received on a sheet of paper was found to consist of hollow spherules of ice, filled with water; of transparent globules of hail, and of drops of water at the point of freezing, which became solid on touching the bodies they fell upon. As it is stated that the thermometer exposed from the windows indicated 30·5°, the temperature of these drops must have been below the freezing point, their solidification taking place, agreeably to the property of water in that condition, on the agitation of their particles occasioned by their impact on the surface upon which they fell. Had the process of freezing proceeded further before the fall of the shower the hollow spherules filled with water would have become ordinary hailstones with a cavity in the centre.

The electrical character of showers of hail has already been alluded to, and is well exemplified by the following account, given by Mr. Howard, of one which fell, with many others, in different parts of England, on the 19th of April, 1807, at Plaistow. Being carefully examined throughout, it presented the following phenomena: When the cloud discharging it—of course a *nimbus* [CLOUD]—"was on the horizon, N.E., and the shower behind it, the pith-balls of the insulated electrical conductor [of Mr. Howard's fixed apparatus for investigating the electricity of the atmosphere] remained in contact. When the extremity of the upper surface of the inverted cone of cloud had arrived in the zenith, they opened *negative*, and diverged slowly to full two inches, at which time pretty strong sparks were drawn from the conductor. During the remainder of the approach of the shower, they gradually closed again. At the moment when the latter [the shower] began to touch the observatory, they opened *positive*, diverged more speedily, and the apparatus gave strong sparks for a considerable time *positive*. As the cloud drew off to the S.W. this change gradually ceased, and the balls opened again *negative*, diverging gradually as before, then converging, and lastly were left a little charged *positive*." In all this, as Mr. Howard points out, we see the natural effects of the high positive charge in the column of falling hail, which may probably have been six or seven miles in diameter, and which appeared to be surrounded with a negative area, extending into the dry atmosphere about three miles in every direction. This very considerable quantity of electricity, and that of some intensity, was conveyed by an amount of hail comparatively insignificant; for when melted into the rain-gauge, together with that of several previous showers, it did not produce more than a hundredth of an inch of water in depth. It is an example of the fact we shall have to consider elsewhere, of how powerful an electrical charge ice is capable of receiving.

Saussure, as cited by Mr. Howard, attributed the greater or less prevalence of hailstorms in particular localities of the Alps to the relation of their electricity to that of the neighbouring mountains, the clouds or storms being either attracted or repelled by them, according as the electricity is similar or opposed to that of the mountains. Borgo Franco, in Piedmont, he had been informed, was peculiarly subject to the calamity of hailstorms; and it has often been observed, he states, that in other plains bordering on high mountains, at a certain distance from the mountains, hail is much more frequent than in places that lie somewhat nearer or more remote. There are distances, too, Saussure adds, that seem privileged, where hail very seldom falls. On an estate on the river Arve, not quite half-a-league from the foot of Mount Salêve, there had not been within the memory of man any considerable fall of hail, the stormy clouds passing always nearer to the mountain or at a greater distance from them.

Arago ('Meteorological Essays,' transl. into English, pp. 106–108) mentions some instances in which the aqueous precipitations from the atmosphere during thunderstorms, whether liquid or solid, have been observed to be luminous, one of which is the luminous rain during a hailstorm already cited from the 'Climate of London.' Among them is one recorded by Lampadius, who was informed by some miners at Freyberg that the small hail which fell during a thunderstorm on the 25th of January, 1822, was luminous when it reached the ground. These cases are doubtless to be explained by the high electrical charge which everything acquires during some thunderstorms; there are experiments with electrical apparatus in which corresponding luminous phenomena are occasioned.

The practice appears to have originated in the last century of making fires on the ground, and of discharging artillery and otherwise exploding gunpowder, on the approach of storms, for the purpose of dissipating them, and especially of preventing the formation or the fall of hail. Arago (loc. cit. pp. 212–218) has given an account of this practice, of the efficacy of which he considers that there is no sufficient evidence, if even the tendency of the evidence is not to show that continuous discharges of artillery may induce local thunderstorms. On the other hand, the experience of the Marquis de Chevriers, in preserving his lands from the ravages of hailstorms by the explosion of boxes of gunpowder, which he caused to be fired on the neighbouring heights on the approach of a storm, while the villages in the vicinity frequently experienced their baneful effects, does not appear to have been sufficiently considered by that philosopher. There are some grounds for believing, also, that the particular conditions of the atmosphere which result in the formation of hail may be counteracted by fires. Matteucci, the eminent Italian physicist, whose electrical researches continue to enrich science, informed Arago that there is a parish near Cesena, in Romagna, throughout the extent of which, for seven miles round, the peasants, by the curé's advice, place at about every 50 feet heaps of stone and brushwood, which they set on fire when a storm is seen approaching. This practice had been in force for three years, during which time the parish had not suffered either from thunderstorms or from hail, although it formerly suffered much every year from hail, and the neighbouring parishes had continued to do so during the period. "Three years," Arago remarks, however, "are not a sufficiently long period of time to allow of any definitive conclusion as to the preserving influence of large fires. The experiment is being continued, and the public will not fail to be informed of the results."

The principle of insurance has been applied to indemnify persons for the very heavy losses sometimes occasioned by these meteorological phenomena, both by the Royal Farmers' and General Insurance Institution and by a society connected with the Norwich Union Insurance Company. The uncertainty which exists in reference to the occurrence of these frequently calamitous storms in any particular locality, and the circumstance that, while no human sagacity can foresee or prevent them, it is utterly impossible to produce them by fraud, appear to render such casualties peculiarly fit, so soon as observation and experience shall have established accurately the average risk, for the application of a principle which has long been applied to casualties of a nature less uncertain, more easily provided against, and which afford greater opportunities for deceit and imposition. The Hail-storm Insurance societies have published chronological lists of the most remarkable hailstorms in this country during the present century, which present an array of destructive calamities far exceeding what might have been expected from their rarity. It is curious also to observe that they appear to have increased in frequency of late years. In one case, which we select solely from the more circumstantial way in which the details are given, many farms of corn were (on the 14th of July, 1824) literally destroyed in Hertfordshire, Middlesex, and Essex; the damage done upon a space of 3487 acres in the last-mentioned county alone was estimated at 14,574*l.*, or about 4*l.* 3*s* 7*d.* per acre, upon an average. It is stated that this was the third time within a period of thirty years that the crops in the north-western part of that county had been destroyed in like way. During the great hail-storms in the months of July and August, 1843, by which immense damage was done in Cambridgeshire, Norfolk, Suffolk, Essex, Hertfordshire, Berkshire, Kent, Oxfordshire, Bedfordshire, Gloucestershire, and Yorkshire, several cases of individual loss amounted to upwards of 2000*l.* The breakage of glass in windows and skylights, and more especially in conservatories and hothouses, is one of the most frequent injuries inflicted by hail-storms, the masses of ice which fall being sometimes sufficient to demolish the wooden framework also. Such extraordinary cases of devastation will be fully accounted for if it be considered that, as it is stated in a paper issued by the Farmers' Insurance Institution, on the authority of Leslie's 'Elements,' "hailstones having a diameter of two inches," a size which has been exceeded in several well-authenticated cases, "will fall with a velocity of 113½ feet in a second, or more than 1¼ mile in a minute." In the hail-storm of the 19th of May, 1809, Mr. Howard's account of which has been given above, it is estimated that 200,000 panes of glass were broken in the immediate vicinity of London alone, besides great damage being done in fields and gardens, and the foliage and branches of trees being cut off. An equal number of panes is supposed to have been broken in the northern suburbs of the metropolis on the 30th of July, 1826. In the denser parts of the metropolis itself less damage appears to be done on such occasions, probably because the vast column of heated air always rising from it alters the local atmospheric condition requisite for the production of large hail.

Hailstones of from six to eight or nine inches in circumference are frequently mentioned as having fallen in this country, in the lists referred to, which are compiled from contemporary publications; and on the 3rd of August, 1824, when the eastern part of Suffolk was visited by a violent hail-storm, by which fowls and game, as well as glass and crops, were extensively destroyed, the ice accumulated in some places to a surprising depth. In many cases a considerable extent of ground has been covered to the thickness of several inches. It is worthy of remark how very large a proportion of the destructive storms are recorded to have occurred in the months of June and July. Without noticing the cases in which two or more storms which occurred about the same time are alluded to as one, which would render this proportion yet more remarkable, the cases recorded in the above-mentioned lists occurred as follows :—

In the month of	January	0
,,	February	1
,,	March	2
,,	April	3
,,	May	7
,,	June	10
,,	July	17
,,	August	4
,,	September	2
,,	October	0
,,	November	0
,,	December	0
		46

The copious lists of hailstorms published by the Farmers' Insurance Institution, which gives references to authorities, and in many cases minute details of the damage done, appeared in the advertising sheet of the 'Farmer's Almanac' for 1845.

Mr. Howard remarks, in agreement with the results in the table just given, that hail is of rare occurrence in the winter, in England; if we except a sprinkling of small opaque grains which in the fore part of the night indicate the approach of a low temperature, and are found on the frozen ground, and on the ice of the ponds in the morning.

Mr. Alfred R. Wallace, in the account of the climate of the valley of the Amazon, appended to his 'Travels' on that river, cites an authentic account of a fall of hail on the Upper Amazon; a remarkable occurrence, he observes, at a place only three degrees south of the equator, and about two hundred feet (only) above the level of the sea. Children were out at play, and brought the hail to their parents, astonished at a substance falling from the clouds which was quite new to them and so remarkably cold. [Ice; Meteorology; Snow.]

HAINAULT SCYTHE. [Harvest.]

HAIR-MANUFACTURES. There is a considerable amount of industry bestowed upon human hair and the hair of certain quadrupeds, in the production of manufactured articles. Some of their uses depend upon the felting properties of a few kinds of hair [Felting; Hat Manufacture]; some upon the great strength of the fibre; and some upon the beautiful gloss of which it is susceptible. Human hair and horse-hair may be taken as the two chief materials for these manufactures.

Human Hair.—The hair-trade is a much more important one than would usually be supposed. It was stated in the 'Quarterly Review' a few years ago (No. 184) that London alone imports more than 100 cwts. of human hair annually, chiefly for making perukes and false curls. The mere clippings would not suffice; there must be a regular *harvest* of hair. A German has had the patience to count the number of hairs in an average adult female head (probably among his own countrywomen), and finds it to be 110,000,—the blonde being most numerous but finer in substance; the red least numerous but coarser. The light hair imported by or for the hair-workers is brought mostly from Germany, by a Dutch company whose agents periodically visit London; the dark hair more usually comes from France. Some years ago, light golden tresses were much in favour, and the German hair had a good market; but now French hair is more used. Young women in England, who have beautiful tresses, are sometimes urged by poverty to part with them for money to the hair-workers; but in France it is a regular system. There are hair merchants in Paris, who send agents in the spring of each year into the country districts to purchase the tresses of young women, who seek to cultivate an annual crop with the same care as a farmer would a field crop. The agents frequent fairs and markets; and have with them a stock of handkerchiefs, muslins, ribbons, &c., which they give in exchange for the hair. So sensitive a barometer is commerce, of slight changes in the value of exchangeable goods, that the agents know the hair of a particular district to be worth a few sous more per pound than that of a district thirty or forty miles away: a fact which naturalists would have been long in finding out. It is estimated that 200,000 lbs. of hair are purchased at each spring harvest. The price paid is about five francs per lb. on an average; but choice specimens fetch much more. The agents send the hair to their employers, by whom it is dressed and sorted, and sold to the hair-workers in the chief towns at about ten francs per lb. That which is to be made into perukes is purchased by a particular class of persons, by whom it is cleaned, curled, prepared to a certain stage, and sold to the peruke maker at twenty to eighty francs per pound. The peruke maker gives it the form which, as is well known, commands a very high price; a peruke is often sold for double its weight in silver. Both of the hair itself, and of perukes and other articles made of hair, France supplies a considerable quantity to England and the United States.

Besides the making of perukes, false curls, &c., hair-jewellery, so called, is another of the minor manufactures from human hair. Bracelets, armlets, lockets, brooches, earrings, and other articles for personal decoration, are made either wholly of hair, or of hair in combination with other materials. No hair-harvest is necessary for a supply of materials; the ordinary clippings are sufficient. The hair goes through numerous manipulations on a small scale. It is laid straight to prevent entanglement; cleaned with warm water and soda; dried on a soft towel; gently drawn between brushes; and sorted into different finenesses and lengths. By the aid of small leaden plummets, pieces of strong thread, and a work-table with peculiar marks and holes on its upper surface, the hairs are made to twist or curl or knot round one another, something in the manner of pillowed lace; a pattern marked on paper or pasteboard being placed on the table immediately beneath the work. For making such small articles as lockets and brooches, advantage is taken of the facility with which hair curls up when a heated iron is applied to it; it depends upon a gradual application of this heated iron to produce the required degree of curvature in the curl. The Great Exhibition in Hyde Park contained specimens of hair-work, representing portraits, trophies, temples, &c., as remarkable for patient industry as for defective taste.

Horse-hair, &c.—Various manufactured articles in horse-hair possess qualities which could not be found in any other substance easily obtainable. The horse-hair differs greatly in length and colour. Some of the white hair from the tail of Russian horses is as much as forty inches in length, possessing great evenness, elasticity, and gloss. Various other kinds, black, gray, and white, come to market in lengths from twenty to forty inches. Some kinds are fitted for the stuffing of sofas and other articles of furniture; while others have the requisite straightness and other qualities for the hairs of violin bows. Horse-hair cloth is woven of hair taken from the tail, mostly of Russian or South American horses. If the hair be naturally white, it admits of being dyed green, crimson, scarlet, &c. by carefully conducted processes; but black or gray horsehairs only admit of a black dye, and these are the kinds usually employed for horsehair cloth. Coloured hair-cloth, mostly made at Worcester and Sheffield, and at Paris, is extensively used in railway carriages and the saloons of steam-vessels, as well as in ordinary domestic furniture. In most cases the best hair-cloth only is made of horse-hair, the cheaper kinds being made of cotton, linen, or worsted; and the brilliancy and permanency of the colours depend as much on these fibres as on the hair. In the weaving of haircloth, the weaver uses a sort of hook-shuttle, which he passes between the threads of the warp from right to left; an assistant places a single hair over the end of the hook, and the weaver draws it through the warp. The process is a very tedious one, for each hair usually constitutes only one throw or thread of weft. Specimens of hair-cloth are made for conversion into carpets. Horse-hair is also made into ropes, sacks, and bags; one manufacturer has made it into muffs. For a cheap kind of stuffing, and as a material in mortar, cow-hair is much used as a substitute for horse-hair. We may mention here that horse-hair is imported to the extent of no less than 20,000 cwt. annually, and that half a million yards of horse-hair cloth are annually exported.

A substitute for hair has recently been introduced as a material for ornamental manufactures. Plaits and curls for head-dresses, as lately observed, are usually made of human hair; but the substitute consists of dyed hemp or flax, aloe fibre, plantain fibre, or China grass. The fibre, when dyed to the requisite colours, is combed or heckled until it presents a glossy surface. To make this into curls, a fixed holder is used, into which is inserted a rod slotted at one extremity. On this rod is placed a tube, slotted at one end and having a pin through it at the other. The fibres, in a damp state, are attached to the slot in the tube; and the tube being caused to turn, the threads assume a curled form, and are attached to the ends of the pin. The tube is then removed from the rod, and a heater inserted to fix the curl in the desired form. The curl is subjected to a final glossing and dressing. There are also attempts now being made to convert the tough fibre of a peculiar South American plant into a substitute for horse-hair.

One peculiar application of hair may be briefly noticed—that of the hair of rabbits and hares, carried on by the Russians. They work up the hair into a kind of felt; press or fashion it into bowls, dishes, plates, and other articles; and varnish it thickly. The materials thus made have the appearance of papier machée or varnished leather, and are strong, light, and durable.

HALLEY'S COMET. [Comets.]

HALO. [Meteors.]

HALOGENS. This term, derived from ἅλς, salt, is employed in chemistry to designate a class of bodies which form haloid salts with the metals. The halogens are chlorine, bromine, iodine, and fluorine, to which may be added the compound halogen cyanogen.

HALOID ETHERS. [Ethers.]

HALOID SALTS. [Salts.]

HAMATHIONIC ACID. [Euxanthic Acid.]

HAMBRO' BLUE. [Colouring Matters.]

HAMMER, POWER, AND STEAM. A reference was made from Forge to the present article. It will not be necessary to notice the hammer as a mere *tool;* but its importance as a *machine* has become such, that a few lines of description are here requisite.

Power-Hammer.—This name we will give to such hammers as can be worked with greater effect than by the mere muscular force of the hammerman, but with the aid of a power other than steam power. Such machines are now used in very great variety. Froming's forge-hammer, applicable to heavy castings, and also to the hammering of edge tools, files, and knives, may be set to work either by hand, water, or steam power; there is a driving shaft which, when once made to rotate by any source of power, effects all the rest, through the medium of a heavy hammer-head, guide-rod, cones, and a vertical spring; the mechanism is subject to modification, by which both the rapidity and the force of the blows can be varied. Hutton's power-hammer is raised by a band, strap, or chain, attached to a drum or pulley on an axis: the ends of the axis are connected with cones driven by bands from any source of power; when the blow is struck, the momentum is made to assist in elevating the hammer again; the axis has an endway as well as a rotary motion, by which one or other of the cones may be disconnected; a handle, commanded by the workman, determines the rapidity of the action of the hammer; and the arrangement altogether is such as to render this machine useful for hammering iron and steel between pairs of dies. Eassie's frictional action hammer, for small general work, can be worked by any continuously-revolving power-shaft, and can be brought up to an activity of a hundred and fifty blows per minute, with a very heavy hammer-head. Cotton's air tilt-hammer, worked by any source of power through the intervention of a shaft, fly-wheel, fast-and-loose pulleys, and cones, is provided with an air-cylinder, to regulate the force and rapidity of the blow; there is a piston-rod in the cylinder, with a piston at the top and the hammer at the bottom; and the admission of air into the cylinder is so regulated as to give complete command over the action of the hammer. Waterhouse's compressed-air forge-hammer, intended for general light work in a smith's shop, and working up to a rapidity of a hundred and fifty blows per minute, acts something in the same way as Cotton's. There are many other kinds; but these will suffice as illustrations of the whole class.

Steam Hammer.—This remarkable and powerful machine, without the aid of which many modern forgings in iron could scarcely by any possibility have been fabricated, is the invention of Mr. Nasmyth of Patricroft. Whatever modifications have since been introduced by other inventors, to him is due the main principle of the contrivance; and there is a good deal of justice in the prevailing appellation, 'Nasmyth's hammer,' as applied to the whole group. Mr. Nasmyth's first patent was taken out in 1842, since which date he has secured several others for minor improvements. A steam-hammer may be said to consist of a ponderous hammer which carries its own steam-engine with it; the cylinder, it is true, is fixed; but the piston always moves when the hammer moves, and a vertical rod connects them both. The action of the steam is *direct* upon the hammer-rod, without the intervention of any levers, fly-wheels, or cranks. The steam-cylinder is supported vertically, at a considerable height above the anvil. The hammer moves up and down in a true vertical plane by sliding in the grooves of a frame; it falls by its own weight, but is lifted by the force of steam driving the piston upwards in the cylinder. The steam is derived from a boiler placed at any convenient distance, through a pipe connected with the cylinder; and there is a complete apparatus of valves, &c., to regulate the admission and shutting off of the steam. As the hammer is in all cases very ponderous, it will fall heavily by its own weight; but the rapidity and force of this fall are susceptible of modification by the mode in which steam is admitted to act above or below the piston. The self-acting apparatus is the most beautiful part of the machine. A workman lightly touches a handle, whereupon the whole internal mechanism so modifies itself, that the hammer will in one instant give a blow sufficient to crush a bar of iron, and in the next a tap so light as to crack a nut-shell without crushing the kernel.

Very numerous minor improvements in steam hammers have recently been made by Kirk, Pearce, Eastwood, Naylor, Morrison, Farrot, Brown, Condy, Sykes, Wilson, M'Dowall, Rigby, and other inventors; but these need not be separately noticed. In some instances the hammer-block constitutes a sort of ram or plunger working within the cylinder, instead of a mass suspended from a piston-rod; some have the hammer, piston, and piston-rod all cast in one piece, to produce firmness in action, and to render the blows more effective; some are so arranged as to increase the fall, or space through which the hammer falls to the anvil—a space which has been made to reach full seven feet: some have the adjusting apparatus so exquisitely arranged, that even a child could vary the force between one blow and the next; some, not intended to equal Nasmyth's in range of application, are made simpler and cheaper for certain special kinds of work; some vary the power and rapidity of the blow without changing the depth of fall, whereas others vary their depth likewise; some economically lubricate the hammer-guides by collecting the grease and oil which fall from the stuffing-box; some are so planned that they can be employed, as occasion may require, in iron-forging, boiler-rivetting, or ore-crushing; some can be worked by compressed air or by steam at pleasure; some have the cylinder placed at the *side* of the hammer, to render less height necessary, and to give more firmness to certain parts.

Steam hammers are now made of enormous magnitude and power. The 50 cwt. 'Nasmyth,' at Portsmouth Dockyard is no longer a marvel of mechanical power. A steam hammer of 120 cwt. has been set up at the Bowling Iron Works, near Bradford. The shaft and crank forgings for the Great Eastern were made at the Lancefield Forge, in Glasgow, by the aid of a 120 cwt. hammer, with 6 feet stroke. Messrs. Morrison, of Newcastle-upon-Tyne, have made a steam hammer for the Russian government, in which the weight of the piston and piston-rod alone is 100 cwt. besides the weight of the hammer; and there is a working space 14 feet in width between the framing of the machine. The same engineers have made a steam hammer for the Mersey Iron and Steel Company, 21 feet high, 14½ feet working space between the framework, a piston 36 inches in diameter, a hammer of 140 cwt., and a total weight of 30 tons. New York possesses a steam hammer with a hammer-head weighing 150 cwt. It is indeed probable that the maximum of size and power has not yet been reached; if greater be required by manufacturers, greater can be produced by the machinists.

HANAPER OFFICE, one of the offices belonging to the Court of Chancery. Writs relating to the business of the subject, and their returns, were originally kept in a hamper, *in hanaperio;* and the others, relating to matters wherein the Crown was immediately or mediately concerned, were preserved in a little sack or bag, *in parvâ bagâ;* whence the distinction of the Hanaper Office and Petty Bag Office, both belonging to the Common-Law and of the Court of Chancery.

HAND-FASTING. [BETROTHMENT.]

HANDGLASS is a name given by gardeners to a portable glazed cover which they place over certain plants for one or two purposes; either to screen them from the effects of cold and wet without depriving them of much light, or to maintain around them an atmosphere of uniform humidity. Bellglasses differ from handglasses in no respect with regard to the purpose they are intended to serve, but instead of being composed of many pieces fastened together, they are blown into shape in a single piece. Glasses of this description are principally used to assist cuttings of plants in the process of striking root, or newly-planted individuals in establishing themselves in the soil. The rationale of handglasses seems to be this:—when cuttings or newly-planted individuals are exposed freely to the atmosphere, they part readily with the moisture they contain, in consequence of the specific power possessed by light, especially direct solar light, of causing perspiration. Under ordinary circumstances the moisture they part with is lost in space, so that it cannot be re-absorbed; and as the atmosphere of the plants or cuttings remains dry, perspiration will go on till the plant is exhausted or dead. The effect of a handglass is to invert this state of things; the moisture raised from the soil by evaporation, or produced by vegetable perspiration, necessarily accumulates beneath the handglass, the air enclosed by which gradually becomes more and more moist, and at last is saturated; this circumambient humidity is re-absorbed by the leaves, or branches, or soil, and thus restored to the plant which had lost it; in addition to which, perspiration itself necessarily goes on the more slowly in proportion as the air itself is charged with humidity. It may also be presumed that a handglass, or any such transparent cover, keeps the temperature in which the plant breathes higher than the external air, and thus stimulates the languid powers of vegetation. Some handglasses are made with either moveable tops, or with a division to open, so as to permit the escape of superfluous moisture or to admit air.

HAND-WRITING, PROOF OF. [EVIDENCE.]

HANSE TOWNS, called also the Hansa, and the Hanseatic League, a celebrated commercial confederacy, which took its name from a now antiquated German word, 'Hansa,' signifying an association for mutual support, in which sense it is used in two charters granted by king John, in 1199, to Dunwich in Norfolk, and to the city of York. The cities of Hamburg, Lübeck, and Bremen were in the middle ages the depositories of the manufactures of Italy and Germany, imported by sea, with which they supplied the northern countries of Europe in exchange for their raw produce. The wealth which they acquired by their commerce excited the envy and the rapacity of the princes and nobles; the imposition of new and the augmentation of old tolls were great impediments to trade, which was likewise rendered unsafe by numerous banditti and pirates who infested the roads and the neighbouring seas and rivers. But it is noticeable that while the towns of South Germany made this mutual protection almost their sole object, those of the north became in a great degree commercial leaguers also. It is not possible to fix the precise year of the establishment of the Hansa; and indeed it is probable that it was brought about by the German merchants who, from different towns, associated abroad. In 1245 the German merchants in England ordered that no German vessel should sail to Lyon, and the order being disobeyed by Rostock, and some other Westphalian ports, the merchants of those places were expelled from the body, which was in the enjoyment of certain privileges, until the transgression had been atoned for. Hamburg and Lübeck, there is no doubt, were the first towns to enter into an avowed union in 1210, to protect the commerce on the Elbe and the German Ocean: the two cities engaged to maintain ships and soldiers at their joint expense, to clear the road between the Elbe and the Trave, and the waters from Hamburg to the ocean, from robbers and pirates; and they further bound themselves to promote their commercial interest, and to defend their rights and privileges. The city of Brunswick, which was used by those two cities as a staple, joined the alliance in 1247; for while Italy was in possession of the trade of the Levant and India, a commercial route was opened, through the upper Palatinate, Franconia, and to the east of the Harz, by way of Brunswick to Hamburg. Other cities soon followed the example of Brunswick, and joined the league. The cities were divided into four classes, or quarters, the chief cities of which were Lübeck, Cologne, Brunswick, and Danzig; and the contingent in money, or armed force, was fixed for each. Lübeck was at the head of the league, issued the summons for the regular assemblies of the deputies of all the cities, which were held once in three years at Whitsuntide (the first in 1260), and also for the extraordinary assemblies, generally held once in ten years, in which they solemnly renewed their league, admitted new members, and excluded those that had not observed all obligations, compacts, &c. Lübeck also had the common treasury and the archives.

In 1261 they established in London their factory called the Steelyard; but German merchants had been in possession of it, or of an adjoining building known as the German Guildhall, for more than a century. An inquisition, quoted in Markland's 'History and Survey of London, of the 28 Henry III.' (1243-4), notices "the Gildhall of the merchants of Cullen" (Cologne), as being in Thames-street, near Dowgate. The number of the towns composing the League fluctuated; probably many which were not entirely free were not recognised as such by the sovereign in whose dominions they were placed, although admitted into the union. Among the principal towns, however, were Bergen in Norway, Berlin, Bremen, Brunswick, Colberg, Cologne, Cracow, Danzig, Deventer, Dorpat, Elbing, Frankfort on the Oder, Goslar, Göttingen, Groningen, Halberstadt, Halle, Hamburg, Hameln, Hanover, Hildesheim, Königsberg, Lübeck, Lüneburg, Magdeburg, Münster, Nimeguen, Osnabrück, Revel, Riga, Ruremonde, Stade, Stettin, Stralsund, Thorn, Venloo, Warberg in Sweden, Wesel, Wisby in the Isle of Gothland, Wismar, Zutphen, and Zwoll in Guelderland. Their four principal factories in foreign countries were at London, Bruges, Novgorod, and Bergen.

This powerful confederacy formed the first systematic plan of commerce known in the middle ages. In its factories a discipline approaching in rigour that of the monasteries was observed, which even extended to the celibacy of factors, clerks, &c. The power of the Hansa rose daily. The cities enjoyed in England the privilege of exporting goods duty-free, and in Denmark of importing duty-free. Their alliance was courted and their hostility feared by the greatest powers. The Hanseatic League defeated kings Eric and Hakon, in Norway, and Waldemar III., king of Denmark, in 1348; they deposed Magnus, king of Sweden, and gave his crown to his nephew Albert, duke of Mecklenburg; they equipped in 1428 a fleet of 248 ships, with 12,000 soldiers on board, against Erick, king of Denmark; and the League concluded commercial treaties with Denmark, Flanders, and England, where Henry III., in 1266, granted them great immunities. But when the roads and seas were no longer insecure; when princes began to be sensible of the commercial interest of their own states; and above all, when the discovery of America, and the way to India by the Cape of Good Hope, gave an entirely new form and direction to commerce, the Hanseatic League gradually declined. On July 25, 1598, the lord mayor of London dispossessed them of the fleet-yard in the name of the queen, who had withdrawn their privileges, and at the last general assembly at Lübeck, the deputies from the several cities appeared merely to declare their secession from the League. Hamburg, Lübeck, and Bremen formed an association in 1614, and remained free republics till December, 1810, when they were incorporated with the French empire, but on the deliverance of Germany in 1813 they were again separated from France, and with Frankfort-on-the-Maine are now called the free Hanseatic Cities of the Germanic Confederation. For a particular account of their connection with England, see STEELYARD. There are numerous works treating of this league. In English, vol. i. of Anderson's 'Deduction of Trade and Commerce' may be consulted. In German, the most important works on the subject are F. Sartorius's 'History of the German Hansa,' 3 vols., 1802–8, continued by Dr. J. M. Lappenberg, 2 vols., 1830–4; 'Die Urkundliche Geschichte des Hansische Stahlhofes,' zu London, 1851, containing much interesting matter relating to the Steelyard in Thames Street; and Mayer's 'Grosse Conversations Lexicon für die gebildeten Stände,' article 'Hansa,' contains a detailed history, with much of the internal constitution of the union.

HAQUEBUT. [ARMS.]

HARDNESS. A term applied to that condition of the force of cohesion in solids where the constituent molecules retain their relative position and resist the application of a force which tends to change the figure of the body. [ATTRACTION.] Hardness is not the same quality as density, since many dense bodies are much softer than lighter ones. Thus glass is harder than gold or platinum, and platinum is harder and denser than gold. Iron and zinc are lighter but harder than gold and platinum. Lead is the softest of the common metals; but potassium and sodium can be moulded between the fingers like putty.

Language is quite inadequate to express the various degrees of hardness in solids. Accordingly the mineralogist resorts to the artifice of selecting a number of well-known minerals as standards of comparison. These are arranged in the form of a scale, known as the *Scale of Hardness* in which each mineral is harder than the one which precedes it, so that each mineral admits of being scratched or having its particles displaced by the one that follows it.

SCALE OF HARDNESS.

1. Talc.
2. Compact gypsum.
3. Calcspar, any cleavable variety.
4. Fluor-spar.
5. Apatite (crystallised).
6. Felspar, any cleavable variety.
7. Limpid quartz.
8. Topaz.
9. Sapphire, or corundum.
10. Diamond.

In determining the hardness of a body, if it neither scratch, nor is scratched by fluor-spar, for example, its hardness is said to be 4, but if it should scratch fluor-spar and not apatite, its hardness is between 4 and 5. The degrees of hardness are numbered from 1 to 10.

The readiness with which some of the metals, steel especially, can be varied in hardness by heating, suddenly cooling, and then tempering, is of inestimable value in the useful arts. Another remarkable and useful property is in some cases developed in the production of alloys. Two metals, copper and tin for example, which are not separately remarkable for either hardness or elasticity, possess these properties in a high degree when combined in certain proportions, forming what is called *bell-metal*. [BELL-METAL.] Hardness is often accompanied by brittleness; but this may be lessened by heating and slow cooling, generally however at the expense of the hardness.

HARE-LIP, a malformation in which the lip is divided in one or more situations by clefts extending from its free edge towards its attachment. It has received this name from the resemblance which it bears to the divided upper lip of hares and other gnawing animals, and is one of the most common of the malformations by arrest of development. [MONSTER.] In the embryo, each lip is formed of four pieces which project separately from the jaws and unite with each other at different periods of fœtal life; but if by any circumstance their healthy development is checked, they remain permanently in the condition which they had at the time of its occurrence. The separate portions of the lower lip unite long before those of the upper, and fissure of the former is so exceedingly rare as to be seldom the subject of treatment. Of the portions of the upper lip, the two middle unite first, and then the two lateral to them; hence a fissure in the middle line is more rare than one on either or each side. Hare-lip may be single or double; that is, there may be one or two fissures—the one may be seated in the middle line of the lip, or opposite to the union of the two incisors with the canine tooth: if there be two, they will be found in the latter situation on each side. It may be simple or complicated with fissures of the gum or palate, which, being developed in an analogous manner, may be influenced by the same cause as the lips, though being earlier united they are less rarely affected.

The cure of hare-lip is important, not only for the uncouth deformity, but because sucking is prevented in infancy, and in later life the speech is affected. It is accomplished by cutting off quite smoothly the opposite edges of the fissure in its whole length, and then bringing them together and maintaining them in accurate apposition till, like the edges of a common wound, they have firmly united. For this purpose, after fixing the portion of the lip with forceps, each edge of the fissure is to be cut off with a knife, or a pair of knife-edge scissors, taking especial care that the wounded surface should be left of the same form and size in each. They are then to be placed in accurate contact by transfixing them with one or two hare-lip pins (according to the length of the fissure), and connecting them with silk wound round them in the form of an 8. These pins should be made of silver, with removeable steel points; the lowest should be passed through full two-thirds of the thickness of the lip, just above its vermilion border, taking care that it penetrates to the same depth in each portion, lest the edge of one should project beyond that of the other. The next pin should be passed midway between the lower edge of the lip and the nostril, and the remaining aperture should be closed with a suture or with sticking plaster. The intervening portions of the lip are now to be compressed by the silk wound about the pins, and additional security is afforded by placing a compress on each cheek, and there bandaging it firmly, so as to prevent the muscles of the lips from contracting and separating the cut edges. After the operation the part should be kept perfectly quiet and cool; in four or six days the pins and other dressings may be removed, and the edges of the wound, which ought to be completely united, will now need only to be secured by sticking-plaster.

When the fissure is double, it is generally advisable to operate first on one side, and when that is completely healed, on the other; but in some cases the whole may be done at once, by cutting off both edges of the middle and each of the lateral ones, and transfixing the whole by the same pins and sutures. In those cases in which a portion of the jaw-bone projects much, it may be sufficient to draw the teeth from it, and then the lip may be stretched to unite over it; but often it will be necessary to remove it by cutting-forceps, or to depress it by long-continued pressure. In all cases it must be remembered, that however wide the fissures may be, there is no loss of substance in the lip; its edges are drawn asunder by the muscles on each side, just as are those of a cut made in a healthy lip (which may indeed require the very same treatment).

The best authorities seem now agreed that after six or eight weeks, the earlier this operation is performed on the infant the better, only avoiding the period of dentition; for besides that very young children are likely to be quiet and asleep all day, and that the healing processes are then very active, it has the great advantage of enabling them to resort at once to their natural food by restoring the power of sucking.

HARLEIAN COLLECTION. [British Museum.]

HARMALINE $(C_{26}H_{14}N_2O_2)$ and *Harmine* $(C_{26}H_{12}N_2O_2)$ are alkaloids occurring in the seeds of *Peganum Harmala*. They are united with phosphoric acid. Harmaline forms yellow salts with the acids, and is transformed into a red matter by oxidising agents. The *harmala red* of commerce is the powder of the seeds. It is used in dyeing red, rose-colour, and pink. It is used in large quantities in Russia. Harmaline yields a number of substitution products, such as *nitro-harmaline*, *cyanoharmaline*, &c. Harmine forms colourless neutral salts which crystallise in long delicate prisms. Harmaline is converted into harmine by oxidation.

HARMINE. [Harmaline.]

HARMONIC PROPORTION. The reciprocals of numbers which are in arithmetical proportion are themselves said to be in harmonic proportion; thus

$$\frac{1}{a}, \frac{1}{a+b}, \frac{1}{a+2b}, \&c.,$$

is a series in harmonic progression.

A line AB is said to be harmonically divided when two points,

C and D, one within it and one on its continuation, are so placed that AC is to CB as AD to DB. In this construction, CD is an harmonic mean between AD and BD, or AD, CD, and BD, are as the reciprocals of terms in arithmetical proportion.

HARMONICA, also written Armonica (from the Greek word for harmony), but more familiarly *Musical Glasses*. Franklin in a letter to Beccaria, says that Mr. Puckeridge, an Irish gentleman, was the first who thought of playing tunes by collecting "a number of glasses of different sizes, fixing them near each other on a table, and tuning them by putting into them water, more or less as each note required; the tones were brought out by pressing his finger round their brims." Mr. Delaval, F.R.S., constructed a set according to the above plan, and showed them to Franklin, who endeavoured to improve the arrangement by mounting a number of glasses on an iron rod by means of a perforation in the bottom of each glass. The glasses partly fitted into each other without touching, and were tuned by grinding, and in this way three complete octaves were got into a small space. The rod was then fixed in a box, and being set in motion the tones were brought out by applying a moistened finger to the surfaces of the glasses. To distinguish the notes the more readily, the glasses were painted inside; each semitone white, and the other notes of the octave with the seven prismatic colours. Franklin describes the tones produced as being superior in mellifluous sweetness to anything he had ever heard before. The arrangement, however, was objectionable on account of its being liable to get out of order, so that the subsequent contrivers of musical glasses have resorted to the original method, which we may here state is nearly 200 years older than Franklin supposed, as may be seen in Harsdörffern's 'Mathematische und Philosophische Erquickstunden,' Zweiter Theil, Nuremberg, 1651. This work is a sort of elaborate "Endless Amusements," and contains a good deal that is really curious and useful, in some cases forestalling modern inventions, which have made more noise than that of musical glasses. Directions are given to take eight glasses of equal size, to tune them by means of wine, and with the wet finger "auf dess Glases Rand herumb fahren, so wirst du eine lustige Wein Musica haben."

Various methods of forming musical glasses have been introduced from time to time, all of them costly except that by Mr. Tomlinson, who selects soda-water glasses, finger-glasses, and tumblers of various sizes, and arranges them in a wooden case, fixing them by means of wooden screws, and bringing them to the same height by means of blocks of wood. The best way to select these glasses is to visit a glass warehouse, and arranging the glasses likely to suit, as to size, on a table, to sound on a flute the note required, and should the note be represented by any one of the glasses, it will speak by sympathy. The reader curious in the subject may be referred to Mr. Tomlinson's 'Student's Manual of Natural Philosophy,' 1838; which contains an elaborate article on musical glasses—their modes of vibration and acoustic properties.

HARMONICS. (Acoustics.) By the harmonics of a musical note are meant all those other notes in which the number of vibrations per second are twice, three times, four times, or any multiple of, the number of vibrations which produce the note in question. Thus the harmonics of a note which is sounded by 200 vibrations per second are those notes which require 400, 600, 800, &c., vibrations per second. The following explanation will be assisted by reference to Acoustics and Temperament. It presumes the reader to be acquainted with the fundamental mathematical laws of the scale. The harmonics of a note are infinite in number, theoretically speaking, and proceed by less and less intervals. And since every note may be considered as identical with any of its octaves, every harmonic has a corresponding note in any given octave. Denoting any key-note by C, and the octave above it by C′, there is no possible sound between C and C′ which is not theoretically either an harmonic of C, or as near to one as we please (which is equivalent to the mathematical proposition that a whole number, divided by a whole power of 2, may be made as near as we please to any given number or fraction).

But, in practice, not only is it impossible to produce any number of harmonics we please, that is, to maintain in vibration any aliquot part we please of a string or column of air, but even among the harmonics which we can produce we find a limit to the number of those distinct harmonics which deserve the name, etymologically considered. Some few of the first harmonics are melodious sounds, considered in relation to the key-note, but others are discordant, and find no place in the scale according to any system of temperament. We shall therefore, taking a given note, say C, simply mention the most important harmonics, and reduce them to their proper places between C and C′.

Let a be the number of vibrations per second which produce C; then $2a$ is well known to produce C′, so that the first harmonic of a note is its octave. The next has $3a$ vibrations, answering to G′; so that the twelfth, or octave of the fifth, is the second harmonic. The third has $4a$ vibrations, and answers to C″, the octave of the octave. The fourth harmonic has $5a$ vibrations, and gives E″, the double octave above the third, in the untempered diatonic scale. The fifth harmonic, with $6a$ vibrations, gives G″, the octave of G′ the second harmonic. In general, every harmonic whose vibrations are an even multiple of those in the key-note, is an octave to a preceding harmonic, and presents no new character. The sixth harmonic, having $7a$ vibrations, is an imperfect (being too flat) double octave to the flat seventh above the key-note, or B flat. This last note, in the common mode of tempering, makes $1{\cdot}77a$ vibrations per second; whereas the same note derived from the harmonic makes $1{\cdot}75a$ vibrations. The eighth harmonic, with $9a$ vibrations, is correctly D‴, or three octaves above the untempered major second. The tenth, with $11a$ vibrations, is a little too sharp for F‴, being $11a$ instead of $10\frac{2}{3}a$. The twelfth, with $13a$ vibrations, is a little too flat for A‴, being $13a$ instead of $13\frac{1}{3}a$.

The preceding summation is useful, as giving an account of the scale of all those musical instruments which consist of one unaltered pipe. These are the bugle, the French horn, the trumpet, and (but for its slide) the trombone; in all of which (except the last) no note can be produced except a harmonic of the fundamental note of the whole tube. Calling the fundamental note C (which however is not very easily sounded), the ordinary scale of these instruments is—

C C′ G′ C″ E′ G″ (B″ flat) C‴ D‴ E‴ F‴ G‴ A‴, in which B″ flat is too flat, F‴ is too sharp, and A‴ too flat. A short pipe however will not produce many harmonics; the bugle goes no further than G″, at least with common lips. Various contrivances have been introduced to extend and correct this scale; the keyed bugle, the use of the hand in the French horn, the pistons sometimes applied to the same instrument, and the short slide of the trumpet, to say nothing of the slide which is the principal distinction of the trombone, will suggest themselves to all who are acquainted with musical instruments. It will be seen under Horn that Mr. Sax has added other contrivances for the extension of the scale. In other instruments harmonics are much used, particularly in those of the violin class, and in the flute. The performance of Paganini upon a single string, which many years ago created great sensation among violin players, arose from an extraordinary power in producing harmonics. In the flute C‴ may be attained without much practice, as an harmonic of the fundamental note of the instrument; and we have heard of players who could produce D‴ and even E‴ in the same way. On the long strings of a piano-forte, as the fundamental note subsides, G′, C″, and E″ may be perceived; and we have heard, among the vaulted roofs of a cathedral, several of the harmonics of the notes sounded in chanting. For further information see the references in Acoustics.

HARMONIUM. This is one of a numerous family of instruments which owe their origin to the invention, or rather the revival, of the *free reed*. There are many claimants to this invention; but, as stated under Accordion, the Chinese were acquainted with it before its introduction into Europe, and the Chinese organ and the musical trumpet depended for their effects upon vibrating tongues of metal. The French, who are often as happy in re-inventing the inventions of other nations as they are undoubtedly clever in their own, claim the free reed; and so respectable an authority as M. Biot ('Précis élémentaire de Physique expérimentale,' Paris, 1817, tome i., p. 386, fig. 50) assigns the invention to M. Grenié, "habile amateur de musique." Biot says, in his usual perspicuous manner, "La languette est une lame de laiton parfaitement plane, et coupée en forme de rectangle, de manière à remplis exactement, ou plutôt presque exactement la face évidée de la rigole." This was in the year 1810; and two instruments were constructed, one of which was sent to the Conservatoire des Arts. In 1827 three free reed stops were introduced into the organ at Beauvais Cathedral, and in 1829 M. Sebastian Erard introduced a free reed stop into an organ built by him for the Tuileries. After this, the free reed gave rise to a number of new instruments, such as the *accordion*, Wheatstone's *œolina*, the predecessor of that exquisite little instrument the Concertina. Many attempts were made to improve the accordion by enlarging and completing its scale, so that it naturally assumed the form of an organ in which a free reed stop took the place of pipes

[Organ], and it was furnished with bellows worked by the foot. Such was the *seraphine.* Varieties of this instrument appeared under such frightful names as *æolophon, physharmonica, æolomusicon, poikilorgue;* also the *melodium* and *symphonium,* the *harmonium,* the *folding harmonium,* or *orgue de voyage,* which brings us to the subject of this article, in which all we can pretend to do is to give some idea of the mechanism by which the well-known musical effects are produced, referring the reader to his own good taste, or to that of his musical friends, in the selection of an instrument among the different clever makers who are warmly competing for public favour. To give a complete account of its mechanism, and the variations adopted by different makers, would require a volume.

It will be understood that the free reed differs from the beating reed in the reed-pipe of an organ in this,—that in the latter case a thin tongue of brass is made to beat on the flattened side of a tube, so as to cover and uncover alternately a slit through which the air passes into the pipe above. In this case the tongue is larger than the opening; but in the case of the free reed, the tongue is a little smaller than the opening, so that when a current of air is projected against it, the tongue yields so as to let it pass; but its elasticity forces it back into the opening, and its momentum carries it to an equal distance on the other side. In this way, so long as the current of air is maintained, vibrations are established, and a series of pulsations produced in the air which, if sufficiently rapid, will produce a musical tone. [Acoustics.] The vibrations of the reed depend for their rapidity on the thickness of the tongue at the free end in proportion to its length: if thick at the free end and thin at the fixed, the vibrations will be comparatively slow and the resulting note deep; if the tongue be thin at the free end and thick at the fixed, a higher note will be the result. The reed is tuned by scraping off a small quantity of the metal at the free or at the fixed end, as the case may be.

The accompanying figures represent the free reed as used in the harmonium: 1 is the brass frame containing the slit; 2 shows the reed in its frame and the method of fastening; and 3 its position in the instrument, the reed being a little below the slit when not in motion. This arrangement produces a more smooth and mellow tone than that of the beating reed, and has the grand advantage of not requiring a pipe, which is an indispensable appendage to the beating reed. The free reed has also a superior power of expression, and any given note, while preserving the same pitch, may be made loud or soft by varying the pressure of the wind; the greater the pressure, the larger the arc of vibration, and, consequently, the louder the note. The arrangements in the harmonium for varying the pressure of the wind, allow of *crescendo* and *diminuendo* effects being produced. There are also means for altering the quality of the notes, while preserving the same pitch, thus giving the varied effects of the organ with the portability of the piano-forte. Variation in quality is produced by making the reeds differ in size and shape.

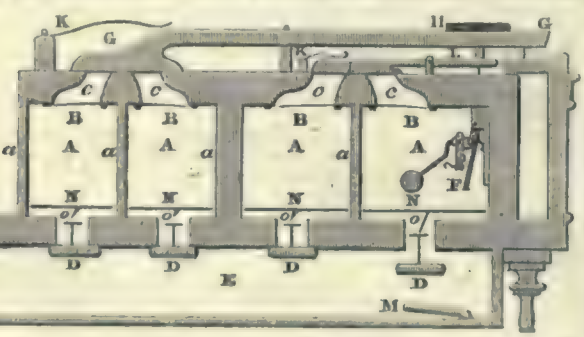
3

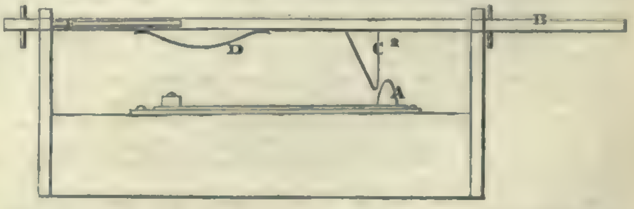
The accompanying figure, which we copy from Mr. Allen's pamphlet on the construction of the harmonium, will show the principal parts of the instrument. The notes are produced by wind which is furnished by means of bellows, worked by the foot, and forced through the valve M into the air-chest E, and thence through the cavities A A, in which the reeds are placed. These cavities occupy the whole width of the instrument, and are separated by partitions *a a*. B B are the reeds, of which there is a complete row or stop in each channel; G is one of the long or white keys, the further end of which forms a valve which closes two of the cavities, and is kept in its position by the spring K. Under and near the front end of the key is a lever, I, which covers two other cavities in the wind-chest, and is also held in position by a spring K. Thus it will be seen that the effect of pressing down any one of the keys is to open all four cavities; but whether the tongues in all of them be set vibrating or not, depends upon what stops are drawn out in front of the instrument. Connected with these stops are four steel rollers, N N, which open the valves D D, and thus admit air from the chamber E into the cavity A, and thence through the slit into *c*, and so out of the instrument after having vibrated the tongue. Each valve D is opened by a small piece of brass projecting from the side of the roller pressing on the piece marked *o*, and each valve is drawn up again into its place by a spring not shown in the diagram when the stop is pushed in.



The wind then being admitted through the slit from A into *c*, the tongue is made to vibrate, but it does so at first in a weak and inefficient manner, and time must be allowed for it to vibrate fully and freely. This is of course a serious defect in a musical instrument, a defect which in the case of the harmonium is overcome by what is called the *percussion action* in which the moment the key is pressed down, a small hammer rises, strikes the reed, sets it in full vibration which is then continued by the escaping wind. On pressing down the key, a button, L, on its under side, presses down a lever I, and this in its turn, forces down the hopper F, which sets the hammer in motion, as shown in the figure. The best harmoniums usually contain twelve stops or draw-knobs, the first of which, *cor Anglais* (bass), and *flute* (treble), is the principal stop. No. 2, *bourdon* (bass), and *clarionet* (treble), is tuned an octave lower than No. 1; No. 3, *clairon* (bass), and *fifre* (treble), is tuned an octave higher than No. 1. No. 4, *basson* (bass), and *hautbois* (treble), is tuned in unison with No. 1. When these four stops are used together, the power is very great. In Chappell's instruments the draw-knobs marked *forte,* communicate with slides which open apertures directly over the reeds, and thus increase the power. By drawing out the knob *grand jeu,* all the stops are opened at once, and great power produced. By drawing out the *expression* stop, there is an arrangement by which the power of any given note may be increased by pressing more forcibly on the foot-board, and in some instruments there is a draw-knob, marked *expression à la main,* by drawing out which the power of a note may be increased simply by pressing strongly upon the key. There is also the *sourdine,* and the *celesti,* for modifying the tone of certain stops.

The harmoniums best known in England are manufactured by Alexandre and Debain, of Paris, the latter maker claiming to be the original maker of the French instrument. In 1841, however, Mr. Evans of Cheltenham produced the *English harmonium,* with two claviers, and two octaves and a third of pedals. This instrument attracted much notice; but it was not brought prominently forward until early in 1859, when Mr. Evans became a steady competitor of the French makers. His object was to overcome the nasal and harsh tones, slow articulation, and other bad qualities of the instruments then in use; and he has succeeded in producing a fine instrument with a good diapason quality, and great rapidity of speech without any loss of power. He has also introduced a wind indicator for removing the difficulties usually felt in the management of the bellows. He has also patented a simple action by which is produced the C C C C (32 foot note) with instant speech; this is an octave lower than has ever been attained by the French instruments.

The means by which the percussion action is got rid of, and a similar effect produced of making the reed or tongue vibrate simultaneously with the depression of the keys or pedals, consists in having a toothed projection attached to a rod or connecting piece, which is moved by the lever extending from the keys; and the projection is so arranged that it works in a mortice formed in the connecting piece, and an extension of it forms a lever, the fulcrum of which passes through the connecting piece, the lever being retained in its place by a spring. When the key or pedal is depressed the connecting piece is moved, and the toothed projection comes in contact with another projection, attached to the free end of the tongue or reed, and as the spring yields, it passes the tongue freely, sets it in motion, and makes it instantly speak. The counter motion for restoring the key or pedal to its ordinary position is a spring or a weight attached to the connecting rod, or the connecting rod may be attached to a pedal or other projection acted on by the feet. The above figure is a side section of the mechanism at rest: A is the projection attached to the free end of the reed; in small reeds for the high notes this projection may be simply a protruding piece of bristle. B is a lever or jack, containing a mortice, in which is a smaller lever furnished with a tooth or projection C², this smaller lever moving on a centre the bearings of which are in B. D is the spring for keeping the smaller lever in position. For pedal action the reeds are arranged vertically, and a lever is attached to the end of the pedal with a connecting rod proceeding to the end of the jack and of the lever, so that when the jack is pulled down it may strike the projection the reverse way to that above described. The arrangement is, of course, applicable to concertinas.

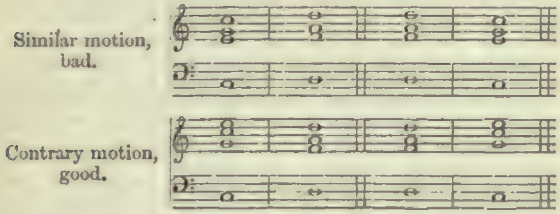


This action is *legato,* not *staccato,* like the percussion, and is therefore peculiarly adapted to pedal-playing. The toothed projection at the end of the vibrator is required in so short a tongue to produce the depth of tone.

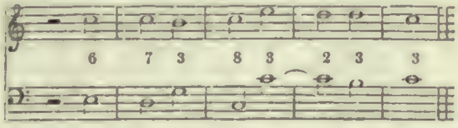
HARMONY (in Music), musical sounds simultaneously produced according to certain rules, forming a chord, or a succession of chords. The simplest harmony, namely the *triad*, or *common chord*, is the result of the vibration of all sonorous bodies, and the foundation on which much artificial harmony is built. Under the word CHORD the reader will find this matter further explained. M. Catel, a modern French theorist of great authority, has divided harmony into *natural* and *artificial*, including in the former all chords not requiring preparation; in the latter, all that are formed by retardation, suspension, &c. But we cannot acquiesce in this arrangement, for it places the chord of the seventh, which is the source of the three real chords of dissonance, in the same category as the triad, or the chord of nature, which of course cannot be admitted. It is true that the chord of the seventh requires no preparation—that is, the dissonant note need not be heard as a concord in the immediately preceding chord [DISCORD]; nevertheless this privilege cannot make natural that which is essentially artificial.

Harmony and *Counterpoint* are now practically considered as synonymous terms, and for some rules concerning the latter, as well as for examples, we refer to that word. [COUNTERPOINT.] To what has been said under the head CHORD, we also again call attention. Chords are the language in which harmony expresses itself, and the laws by which the one is governed regulate the other also. Besides the rules given under different heads in this work, we here add the few following:—

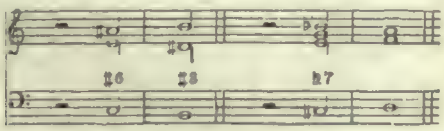
1. No two perfect concords, namely two 5ths or two 8ths, are allowed to succeed each other in the same progression, but are permitted in contrary motion; that is, when the one rises and the other falls. Examples:—



2. Most discords require to be *prepared*, and all must be *resolved*; that is, the dissonant note is to be first heard as a concord, and after *percussion*, or being sounded, must pass into a concord, generally by falling a tone or semitone. But sometimes the resolution is brought about by the base, as in the instance of the discord of the 2nd. Examples:—



3. It is in the nature of sharpened intervals to rise, and of flattened ones to fall; but extreme sharp intervals almost invariably must rise, and extreme flat ones as invariably must fall. Example:—



These examples will also show a reason for giving two names and appearances to that which is, practically speaking, one and the same note; though, theoretically, A sharp and B flat are different sounds.

4. In music in four or more parts, the parts should be dispersed, or separated, in a manner as nearly equal as possible: thus a more perfect symmetry is obtained, and a richer harmony produced. But with a view to some particular effect, a very different distribution of the parts is occasionally made.

5. As a general rule, every composition, whatever its kind, is to commence in its key; but as regards the termination, the rule is without exception, and peremptory: though sometimes the third is changed, from minor to major.

To enter fully into the subject of harmony would be to give a treatise on musical composition. The symbols of harmony—or certain figures, some written, some implied—will be explained under THOROUGH-BASE, an inadequate and unmeaning term, but so firmly fixed that it could not now be changed for a better. For the accompaniment of the scale—*La Règle de l'Octave*, as the French call it—a very important study when properly carried out, see ACCOMPANIMENT.

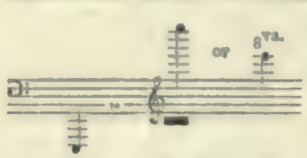
That the term *harmony* was not used in the same sense by the ancients as by the moderns, seems now to be generally admitted, but admitted without at all affecting the long-disputed and, we believe, undecidable question, as to the knowledge of counterpoint possessed by the Greeks and Romans, or compromising any opinion delivered or entertained on that obscure and perplexing subject. By Harmónia (ἁρμονία) the Greeks meant simply to express the proper relationship of one sound to another, the pleasing agreement of intervals in a melody, and nothing beyond. Though, however, they employed the word harmony in a very different sense from that given to it in later ages, it does not thence necessarily follow that they were ignorant of the high branch of the science to which we apply the term. That they played and sung in octaves is undeniable; and it is almost equally certain that they occasionally used simultaneous thirds, instrumentally and vocally. It seems unlikely, then, that so active, so ingenious, and musical a people, furnished with an abundance of many-stringed lyres, of double flutes, as well as other instruments, should not have discovered, even by mere accident, something of harmony, and have been led to investigate its nature and cultivate its practice. But on the other hand, if they were acquainted with the effect of combined sounds, and, as a sure consequence, had converted their knowledge to some useful purpose, they would almost certainly have left, among the numerous disquisitions and lengthened conversations on the subject of music which have reached us, some undeniable evidence of so important a fact.

HARP (heaꞃp, *hearp*, Saxon), a musical instrument which, under different forms and denominations, may be traced to the remotest ages. According to Holy Writ, Jubal, seventh only in descent from Adam, was its inventor; he "was the father of all such as handle the *harp* and organ," as Moses tells us. Notwithstanding the wonders related of Amphion's lyre, or harp, we are compelled to believe, judging from representations in sculpture and on coins, that the Greeks themselves did not so much improve the instrument as their writings would lead us to conjecture. But there now seems to be little doubt that the Egyptians brought the harp to a comparatively high degree of perfection: the fresco painting discovered by Bruce near the ruins of Thebes, which he thinks was executed by order of Sesostris, who reigned between fourteen and fifteen hundred years before the Christian era, exhibits a harp so much resembling that of the present day, in form, dimensions, and ornament, that it might, upon a hasty inspection, be mistaken for one of modern manufacture. He describes it as wanting the pillar, an omission, most likely, of the painter. "The back part," he says, "is the sounding-board, composed of four thin pieces of wood, joined together in form of a cone, that is, growing wider towards the bottom. . . . . . Besides that the principles on which the harp is constructed are rational and ingenious, the ornamental parts are likewise executed in the best manner. The bottom and sides of the frame seem to be veneered, or inlaid, probably with ivory, tortoise-shell, and mother-of-pearl, the ordinary produce of the neighbouring seas and deserts. It would be now impossible to finish an instrument with more taste and elegance." This account, among others by the same, was at first received with some suspicion; but later travellers in Egypt, among whom is Denon, have vindicated Bruce and confirmed his statements. Rosellini too, one of the best authorities, in his work, 'I Monumenti dell' Egitto,' &c., Pisa, 1832, has given coloured engravings of harps corresponding in nearly all respects with the instrument designed and described by Bruce, thus proving the great superiority of the Egyptian harp over every instrument of the kind known to have been in use among the Greeks or Romans.

Many learned persons, observes M. Ginguené, are of opinion that the Europeans are not indebted to the Egyptians for the harp, notwithstanding the resemblance of the instruments used by both the former and the latter; they believe that it originated in the north, that it was introduced into England, and subsequently into Ireland, by the Saxons and other piratical hordes from the Baltic. Martianus Capella found it among the northern tribes which overran the Roman empire in the fifth century. Jones, the Welsh bard, claims for his country the possession of a harp of twenty-six diatonic notes, so early as the beginning of the sixth century, and moreover adds that musical compositions proving the validity of his claim were extant in his time. But he offers no authority for the statement. The Irish were well acquainted with the harp from a very early period, and it appears probable that harps of the Egyptian kind were known in Ireland long before our æra. In Bunting's 'Historical and Critical Dissertation on the Harp' is an engraving and description of an ancient Irish one still in being, though in an imperfect state. It had in a row forty-five strings, and an additional seven in the centre, as unisons. Its form is not unlike that of the modern instrument, but the pillar is curved outwards, and in point of workmanship the whole is remarkable "both for the elegance of its crowded ornaments and for the general execution of those parts on which the correctness of a musical instrument depends." Its height is 3 feet 10 inches, and the longest string is 3 feet 4 inches.

The Welsh triple-stringed harp of the present day extends from G an octave below the first line in the base, to G or A in altissimo on the *right* side; and from G, the first line in the base, to the same upper notes on the left hand; the middle row consists of the semitones of the outward rows. Hence, if the outside rows be tuned in the diatonic scale of G, each parallel note being in perfect unison, the notes of the middle row are tuned a semitone higher; "that is, C is made sharp, &c., so that in modulating from the key of C to that of D, the performer introduces a finger between the C natural and D of the outside strings to strike C sharp, which is in the middle row."

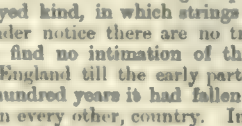
The harp, as a generally useful instrument, may be said to date its existence from the time when pedals were added to it. With these it is possible to modulate into all keys, and to execute any music suited to keyed-instruments. We are indebted for the present improved and nearly perfect state of the harp to the late M. Sebastian Erard, who, in 1794, took out a patent for a harp with seven pedals that rendered the chromatic scale. This was a single-action-harp, the pedals only effecting one change on the strings. In 1808 the same mechanist produced his double-action harp, the pedals of which have two actions. This last is tuned in the key of C flat. By fixing the pedals in the first groove the instrument is at once transposed into C natural; and by fixing them in the second groove it is transposed another semitone higher, into the key of C sharp. The compass of the harp thus improved is from double E below the base to E in altissimo; or—



But though the harp in this highly improved state may be used for the performance of any music written for the pianoforte, yet in executing compositions in which there is much modulation, the difficulty is of an extreme kind, and indeed unconquerable except by devoting more time to practice than ought to be bestowed on an accomplishment, however elegant and fascinating.

In the construction of the harp there are many ingenious mechanical contrivances which would repay the study of persons fond of such investigations: there is also much skilful workmanship required. The name of Erard is still one of power in connection with this instrument. At the Great Exhibition of 1851, Mr. P. Erard received the Council Medal for his pianofortes, and on "account of the great merits of his harps the jury included them in the award." Messrs. B. Jones are honourably mentioned for an improved triple strung Welsh harp, and a Spaniard named Gallegos received a prize medal for an ingenious specimen of *harp-guitar*.

HARPSICHORD (originally, and with some reason, written *Harpsicon*), a keyed musical instrument, in form the same as the grand pianoforte, but smaller, strung with steel and brass wires, two to each note, which were struck by *jacks* armed with small pieces of quill, acting as *plectrums*, and thus made to render a brilliant but somewhat harsh sound, wholly unlike that produced by the hammers of the piano-forte. The compass of the harpsichord did not at first exceed three octaves, but by degrees was extended to five, from double F below the base to F in altissimo: or—



All harpsichords had *stops*, which increased or diminished the string power: they also were generally furnished with a *swell*, or a means of opening and closing the lid: and many were supplied with two rows of keys, the upper acting on a separate set of strings, which gave a very soft sound, intended as an imitation of a muted violin, &c.

The period at which the harpsichord was invented is quite uncertain. It is not absurd to surmise that the organ speedily suggested some instrument of the keyed kind, in which strings were substituted for pipes, but of that under notice there are no traces before the 15th century. Indeed we find no intimation of the harpsichord having been introduced into England till the early part of the 17th century; and in less than two hundred years it had fallen into disuse in this, as well, we believe, as in every other, country. In 1838, Mr. Moscheles, wishing at his *Soirées Musicales* to perform some of the lessons of Scarlatti, Handel, and Seb. Bach on the instrument for which they were written, had great difficulty in finding, in the vast city of London, a harpsichord to enable him to accomplish his purpose. Several other stringed instruments struck by *plectra*, were, together with the harpsichord, superseded by the superior *action* of the PIANOFORTE.

HARQUEBUS. [ARMS.]

HARTIN ($C_{20}H_7O_2$). A white crystalline resin extracted from lignite.

HARTITE. A resinous matter very similar to *hatchetin*.

HARTSHORN, SPIRIT OF. [AMMONIA.]

HARTSHORN, the horn of the *Cervus Elaphus*, the hart, or common stag [DEER], which has a place in the pharmacopœia, because it contains less earthy matter, and more gelatine, than other bones. It is kept in the form of shavings, of which a sufficient quantity boiled in water yields a jelly suitable to convalescents, which may be flavoured with lemon-juice or wine, &c; but there is no proof that it is superior to jelly made from calves' feet. It is sometimes a useful addition to milk for young children, but it possesses no alkaline properties, and the further addition of a little lime-water is often necessary to fit it for irritable stomachs. The decoction of hartshorn is often used by brewers to clarify beer and other liquors, as being cheaper than isinglass (Pereira). The pungent volatile salt, called smelling-salts, retains the name of hartshorn from being originally obtained by distillation of this horn. [AMMONIA.]

HARUSPICES, a class of priests in ancient Rome, whose principal duty was to inspect the entrails of the victims which had been sacrificed, and thereby to foretel future events. They also interpreted various phenomena, such as lightning, earthquakes, &c. (Cicero, 'Cat.' iii. 8; 'Div.' i. 41.) This art, called *Haruspicina*, was derived from Etruria, where it is said to have been discovered by one Tages. (Cic. 'Div.' iii. 23.) The Romans used frequently to send their children to Etruria in order to be instructed in this art (Niebuhr), or as others read the passage (Cic. 'Div.' i. 41) caused a number of young Etrurians belonging to Roman families to be so instructed; and Etrurian haruspices often practised their profession in Rome. The duties of the haruspices in many respects resembled those of the augurs; but they were not reckoned so important, and they never acquired that political influence which the augurs possessed. [AUGURS.] They were formed into a college or corporation at Rome, of which the chief was called "Summus Haruspex," or "Magister Publicus." Their art fell into disrepute among the well educated Romans in the later times of the republic. Cicero ridicules their pretensions of foretelling future events, and relates that Cato used to say that he wondered how one haruspex could meet another without laughing. (Cic., 'Div.' ii. 24.) The Emperor Claudius wished to revive the study; and under his directions a decree of the senate was passed for that purpose (Tac., 'Ann.' xi. 15); but it probably produced little effect.

HARVEST is a most important period to the husbandman. When by his skill and industry the ground has been well prepared to receive the seed, and every circumstance has been favourable to the growth and ripening of his crops, he may be deprived of a great portion of his reward by an unseasonable time of harvest. Although the state of the weather be beyond his control, he may, by an attentive observation of the usual changes at particular periods of the year, anticipate its influence in any particular situation. The precautions which are necessary in a northern climate, where the fruits of the earth come late to maturity, would be superfluous in more southern latitudes. It is from the inhabitants of northern and mountainous countries that we are likely to learn the means of obviating the effects of an unfavourable season and a late harvest.

In those southern climates where the heat and drought are not too great for the growth of corn, the only care of the farmer is to procure hands sufficient to reap it. The heat of the sun and air soon dries the straw and hardens the grain. A spot is levelled in the field, and the corn is threshed out immediately, either by the tread of cattle driven over it, or by the flails of numerous threshers. The corn is winnowed and stored in granaries; and the straw is reserved till winter, when it forms the chief fodder of horses and cattle. In these regions the harvest is a continual feast; no ungenial weather disappoints the hopes of the husbandman. But in northern climates, where the harvest is later, and cold rains and storms are frequent in autumn, ingenuity is often taxed to save the corn from being entirely spoiled, after it has been severed from the ground; roomy barns are erected to secure it in the straw, till it can be threshed; and the joy of harvest is frequently interrupted by the anxiety which is the consequence of sudden changes of weather.

To lessen the casualties of harvest in a moist climate, the experienced husbandman endeavours to arrange the time of sowing each kind of grain, so as to ensure their coming to maturity in a regular succession. Thus he has more time to attend to the precautions of which experience has taught him the utility; and if the duration of harvest is longer, there is less danger of all his crops being spoiled by a wet season.

It was long the custom through the whole of the north of Europe to store all the produce of the farm into barns, especially the corn; and it was thought that as soon as the sheaves were collected under a roof, all danger was past. The increase of the produce raised on most lands by an improved system of agriculture gave rise to the practice of stacking corn in the open air, and securing it by a covering of thatch. It was soon found that the grain thus stored in the straw was better preserved than that which was in the barn; and the invention of stone, or cast-iron pillars, as supports for the frames on which the grain was stacked, not only secured it from the depredations of vermin, but kept it in a much drier state than when the stacks were made on the ground. This was a great improvement; and now, in the best managed farms, the only barns required are those in which the corn is threshed; and if there is sufficient room to hold the contents of one stack of the usual dimensions, it is all that is absolutely required.

The want of room in the barns was probably one of the reasons why the reapers were permitted to cut the straw half-way between the ear and the root, leaving more than half the straw in the field. Another reason also was the profusion of weeds which grew amongst the corn, and which retarded its drying, by retaining the wet much longer than the ripe straw. It was thought also that the seeds of weeds were thus prevented from mixing with the grain in the threshing, and giving more trouble in the winnowing. The usual prohibition against selling any straw also made the farmers less careful to secure the whole. The stubble was mown after harvest, and formed into broad walls, called in some places *haulm-walls*, round the yards where the cattle were fed in winter, for the double purpose of fodder and shelter. But it is evident that this practice is defective; there can never be too much straw to be converted into manure by the dung and urine of cattle, and what is left as stubble is much wasted before it is mown and carried into the yard. The seeds of noxious plants remain on the land, whereas they would be much more effectually destroyed if they were stacked with the corn. The subsequent separation of them is a very trifling additional labour where a winnowing-machine is in use. It may therefore be admitted as a general rule in reaping, to cut the straw as near to the ground as possible; this, if done by hand, is best done by an instrument called a *cradle scythe*, which mows the straw, and collects it so as to be readily gathered into sheaves.

The Hainault scythe has a very short handle, and is used with one hand, while the other collects the straw into a sheaf by means of a large hook at the end of a wooden rod. It is a most useful instrument, and greatly preferable to the fagging-hook in use in Middlesex and the neighbouring counties, where straw is valuable and sells at a high price. It cuts more straw at each stroke, and is less fatiguing to the reaper, because his position is nearly upright when he uses it. In many places it is not usual to tie up any corn into sheaves, except rye, wheat, and beans. Barley and oats are usually mown, raked into heaps, and carried into the stack or barn when dry, like hay; but this is a slovenly practice, which should not be recommended. With good tillage and proper manuring the straw of barley and oats will be strong, and of sufficient length to require being tied up into sheaves; and much less of the grain is shaken out and lost in this way than by the usual method.

The rapidly increasing, and soon to be universal, practice of harvest work will be to cut all corn by the reaping-machine, of which a description will be given in its place. [REAPING MACHINES.]

In rainy seasons it frequently happens that the sheaves remain a long time in the field before they are sufficiently dry to be carried and stacked. If the ears are not secured from the wet they become soaked, and the grain sprouts in the ear. This is a great loss; for sprouted grain is very inferior, and can only be sold at a low price. A little attention will often prevent the bad effect of rains. In some places six or eight sheaves are set up in a circle, with the butt-ends diverging, so as to admit the air to circulate among them; a sheaf is opened by spreading out the ears, and is placed inverted over the ears which lean against each other, forming a truncated cone. In others four sheaves thus placed are covered by other two, ears downwards, and the whole bound together by a band. Thus the butt-end of the top sheaf is the only part in which the rain can lodge: and the first sunshine will soon dry this; the rain runs off the sides of the inverted sheaves, and the ears, pointing downwards, will not long retain the wet.

When the stack is building, the butts of the sheaves are placed outwards, and project gradually over the sides of the frame, and over one another, so as to build the stack in the form of a bowl, with a cone or pyramid over it, according as the frame is round or square; this is carefully thatched with straw, and the outer surface is cut smooth by means of shears. This not only saves all the ears which chance to lie outwards, and which would have become the prey of birds, but it also prevents the rain from beating into the stack and injuring the corn. It may then be considered as safe.

Where there are no raised frames, and the stack is built on the ground, or on a bottom made of faggots, to keep it dry, a belt of plastering or stucco is sometimes laid, a foot wide, round the stack, about 18 inches from the ground, after the surface has been cut quite smooth and even. This contrivance is intended to prevent the rats from lodging in the stack, and it is very effective. A frame made entirely of iron, and supported upon iron columns, has lately been invented. It may be readily taken to pieces and put together again when it is wanted. The advantage of it is, that it is cheaper and more easily moved than any other; and it is very convenient for a temporary purpose.

Harvest is proverbially a joyous time, and one when hospitality is practised with more good-will than at any other season. The custom of giving a supper to the harvestmen and women, when the last corn is carried, has been observed from time immemorial; and it is much to be regretted that in many farms it is now omitted, or a mere gratuity is given instead. The community of good feelings which ought ever to exist between the master and his servants or labourers, is most effectually kept up by occasional friendly intercourse. The anticipation of this enjoyment was an incitement to exertions in the field; and the farmer was amply repaid the expense which the feast occasioned. The stimulus of strong beer is still applied at harvest, and frequently to such a degree as to defeat its own object. In some places the labourers have a certain sum in addition to food *to finish* the harvest, whether it is a longer or shorter time. In others they have the usual weekly wages, and a gratuity at the end, with plenty of beer so long as it lasts: accordingly as labourers are abundant or not, the price is less or greater. Many thousands of Irishmen still come over to England and Scotland in the time of harvest, and are of great use in finishing it in a short time.

The processes of harvesting the several grain and root crops are described in detail under their respective names. The above remarks apply generally to the cereal grains. The period of ripeness at which each should be cut is important, as affecting the ultimate quality of the sample. The last process of ripening seems to consist in the growth of the outer skin of the seed, which is the bran of the miller. An early cutting of wheat is important, as hindering an excessive growth of this bran. Oats need to be cut early, as, if ripe, a great deal of the grain is lost in windy weather. Barley, which for malting purposes needs to be all of one ripeness, is secured in that condition by allowing it all to become dead ripe, which is indicated by the downward pointing of the ear. Beans and peas are better cut before becoming dead ripe, as their straw is then more valuable for fodder.

HAT MANUFACTURE. Hats are made of wool, fur, silk, straw, and many other substances. The material chiefly used in making straw hats is wheat-straw plaited in strips and sewed together in the required form, in the manner described in STRAW PLAIT MANUFACTURE. Silk hats are composed of a form made of chip, stiffened cotton, or felt, and covered with woven silk plush or shag, fashioned to the required shape and drawn over the form. There are three descriptions or qualities of hats made of wool, namely, beaver-hats, plait-hats, and felt-hats. Each of these has the body composed of felt: the first has a covering or nap of beaver; the second, a nap of the fur of the musk-rat, or the neutria, or some other fur of small value; and the third kind is without a nap. It will be sufficient to describe briefly the chief points of difference in these.

Beaver Hats. The curious art of *felting* is believed to have been brought to Western Europe by the Crusaders, who found the tents of their enemies covered with that substance. Wool in the yolk, that is, with the natural grease, will not felt; and it is necessary to the process that it should be well scoured, when the fibres being brought together have a tendency to mat or interlace. This tendency is so strong that it is not possible to spin woollen yarn without previously oiling the wool. Hats of the very finest quality are made with lamb's-wool imported from Spain or Saxony, and the fur of English rabbits. The nap is composed of the fur of the beaver and neutria and the down from the back of the English hare mixed together. To form the body of the hat the wool and rabbit's-fur are separately *bowed* in the manner employed for freeing cotton from its seeds [COTTON.] The two substances (about 2¼ oz. for one hat) are next bowed together until they are intimately mixed; after which the mass is spread evenly, covered with an oil-cloth, and pressed, first gently and afterwards more strongly, by which means the fibres will become tangled or interlaced. A very loose and imperfect felt is thus produced, by reason of that peculiar property which is described under FELT AND FELTING, and the cause of which may be understood from the annexed magnified view (*fig.* 1) of a fibre of fur. The next process is to cover the felt with a triangular piece of damp brown paper, and then to fold it in a damp cloth and work it well with the hand, pressing and bending, rolling and unrolling it, until the interlacing or felting is much more perfect, and the mass becomes compact. The felt thus prepared is in the form of a large conical cap; it is taken to the wide brim of a boiler charged with water and beer-grounds and a small quantity of sulphuric acid. In wine countries the lees of wine are substituted for beer grounds. This mixture is kept nearly to the boiling point. The workmen, having the palms of their hands protected by a covering of thick leather, lay the felt on the margin of the boiler, and then proceed to sprinkle it with the hot liquor and to work it about with their hands; by this means it shrinks and becomes more compact. It is then dipped into the boiler and worked, first with the hands, and next by the help of a rolling-pin, which admits of more force being used; and this process is continued until the felt no longer contracts. Considerable skill is required in thickening that part which is to form the brim. After being worked about in this way for some time, it is found that the cap, by the continued influence of heat, moisture, pressure, and friction, has been reduced to one-half its former dimensions, but doubled in thickness.

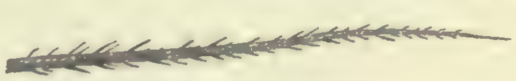


Fig. 1.—Fibre of beaver-fur magnified.

The next process is that of stiffening. The substance employed for this purpose is a varnish composed of several gums and resins, a solution of which is applied by means of a brush to one side, and sometimes to both sides of the felt. After this it is stoved, by which the whole substance becomes duly impregnated with the resin.

We have now to attend to the outer covering or glossy surface. To form the nap of a hat, one-half or three-fourths of an ounce of beaver, and some other less costly fur, are required. The fur has previously been carefully prepared. It is cut from the pelt or skin by a beautiful machine adverted to in the article FURRIERY, and shown in *fig.* 2;

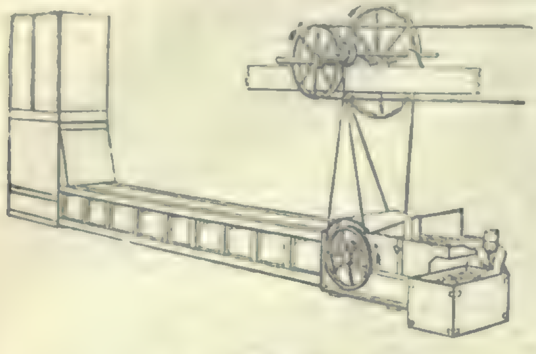

Fig. 2.—Fur shearing machine.

after which it is sorted by the machine shown in *fig.* 3, described in the same article. When ready, the fur is bowed and imperfectly felted in the manner already described, and shaped the same as the body to which it is to be applied, but a little larger. The body is softened by immersing it in the boiler; after this the nap is applied and worked as in felting, until the required union is effected between the two bodies. A narrow strip of beaver is felted round the inside of the cap, to form the underside of the brim. During the felting, the fibres of fur become driven in between the fibres of the felt body, and firmly interlocked.

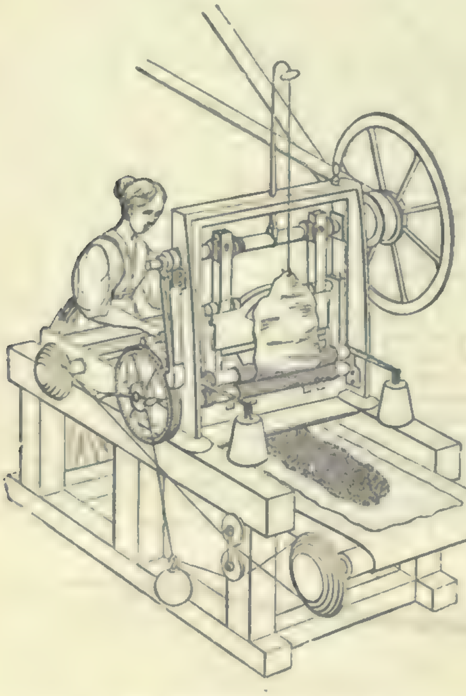

Fig. 3.—Fur separating machine.

The felt thus covered is in the form of a cone, and must be brought to the cylindrical shape in which it is worn by means of a wooden block of the requisite form. This operation, which is called blocking, is performed by working it with the hand on the block to which it is tied. The hat is then combed and sheared; after which it is dyed in a bath composed of water, logwood, sulphate of iron, verdigris, and gall-nuts, in which the hat is boiled during some hours; it is then drained and dried. After this it is softened by steam, the crown is strengthened by placing in it a disc of scale-board, and linen is pasted over this. The nap is raised, and a uniform direction given to its fibres by means of warm irons and hair brushes. The last processes are binding and lining; when the hat is ready to be worn. A good beaver hat passes through the hands of not fewer than twenty or twenty-five workmen during the process of manufacture.

Plaited and Felt Hats.—The beaver hats, just described, although the best results of the hatter's art, are very little worn at the present day; their commercial importance is therefore small. In every way the use of them has lessened. Originally the foundation, as well as the napping, was made of beaver fur; then there was a substitution of fine wool and coarse fur for the foundation; then a mixture of cheek beaver and common beaver for the best fur, as a napping; and lastly, a combination of a very small portion of beaver with neutria, musquash, hare's fur, and wool. About the year 1830 it was estimated that a million beavers were annually killed to supply the hat-trade in Europe; but in 1860 it is believed that little more than one-twentieth of this quantity is thus used. The *plaited* hats, in which coarse and cheap fur are employed instead of costly beaver, are made nearly in the same way, and have been equally affected by change of fashion. The revival of the old *felt* hats, or the use of such hats by persons who would formerly have scorned to wear them, has given a great impetus to this particular branch of the manufacture. Here no fur is employed. Wool, of a greater or less degree of fineness, according to the price to be charged, is felted into a compact body; and this body is either blocked into the regular hat shape, or is made to assume one of the many varieties of slouch or 'wide-awake' forms. It may be mentioned here that in America felt hats are now made by machinery.

Silk Hats.—These have become by far the most important article in the manufacture, so far as concerns extent of production. Silk is wholly incapable of *felting*, and therefore cannot be applied to a hat in the same way as wool or fur. A silk hat consists of a non-felted body covered with a non-felted hood of silk plush. Willow, cane, chip, stiffened cambric, horsehair, mohair, and many other substances are employed for the body or foundation. The body is made by shaping round a block, and using a substance of extra thickness for the brim. A varnish cement is used to join the various parts; and a resinous stiffening composition is laid over the outer surface. To aid the adhesion of the silk plush to the body, the latter is coated with a peculiar varnish, which, being softened by a heated iron after the plush is laid on, causes the two to adhere closely. The fixing of the plush is the most difficult part of the manufacture. The silken fabric must not only be made to adhere in every part, but the seam or joining up the side of the hat must be rendered as imperceptible as possible. The plush is in the first instance sewn by women into the form of a hood or covering for the hat; but there is no sewing at the meeting-edges up the side; they are brought together, pressed down with a heated iron, and the silk shag brushed over the joint. Their junction can always be seen in a silk hat, however cleverly made. The large increase in the manufacture of silk hats within the last few years, has resulted chiefly from the use of a waterproofing composition previous to the application of the plush; the elastic gums, when dissolved in naphtha, impart a body or substance to the foundation, which enables the makers greatly to reduce the quantity of material employed in making it, thus at once cheapening the hat and making it more light and elastic. The same quantity will now work up into more than twice as many hat-bodies as were producible by it twenty years ago. Plush is largely made in England for covering silk hats; but the best, for the so called 'Paris hats,' comes from France, whence nearly 200,000 lbs. of black silk plush are yearly imported for this purpose.

Cork Hats, &c.—The novelties introduced or proposed within the last few years in the hat-manufacture are very numerous; but we can only glance slightly at some of them. The lightest hats made are those in which the foundation is of cork, cut into very thin sheets by a sort of veneer-cutting machine; but though light, they are not yielding, and not well suited to maintain their shape. One novelty in felt hats consists in producing the shape by a kind of die and counter-die, one of which forms the convex and the other the concave side; the dies are heated by steam, and the combined heat and pressure force the felt to assume the desired form. A somewhat similar method is that of forming a hat in one piece without joining; the felt, cloth, or other material, after being dressed with an adhesive solution, is stamped into form between a heated mould and a heated plunger; the hat might even receive a pattern or device on its surface, if the mould were engraved or embossed; and a waterproofing solution might be applied either before or after the stamping. One inventor proposes to employ a former or core of perforated metal; this former rotates in front of a trough containing wool or hair; a revolving fan sucks the air out of the former, and draws the fibres from the trough until they are deposited in a layer on the perforated metal, where subsequent processes cause them to felt together into a hat-body. Some hats are made with a complicated system of springs in the foundation, to facilitate the folding up of the hat into a flat form for placing under the arm or on a seat. A contrivance having a similar object in view has been introduced, consisting in cutting the body quite through, at the lines intended for the creasing; the edges are then cemented by covering them with a thin strip of India-rubber, leaving the edges a little way apart. A suggestion has been made for using palm-leaf, or the Brazilian grass-plait, as the foundation for a hat; the material to be plaited to something like the necessary form, then shaped on a block while moistened by hot water, then strengthened with tapes at the edges, and then stiffened and rendered waterproof; it is conceived that such a hat, coated with silk plush, would be light, soft, easy, and durable. Some hats are rendered 'ventilating' by cutting a circular hole in the foundation, and hiding it with the silk plush; while others exhibit a complicated structure of the brim and sides for the attainment of this end.

The export of hats now amounts to about 130,000 dozens annually, nearly all to the British colonies.

HATCHETIN. A fossil resin found in the lignite of Wales. It is colourless, fusible, and volatile; and is probably identical with *ozokerite*. It has the same per-centage composition as olefiant gas, but is doubtless a mixture of several chemical compounds.

HAUTBOIS. [Oboe.]

HAWKER. [Pedlar.]

HAWKING. [Falconry.]

HAZEL. *Economical Uses.* The hazel is best known for its *nuts*, which are consumed in enormous quantities. From Spain alone there are usually exported 30,000 or 40,000 bags in a year, of four bags to the ton. Besides being eaten simply as a fruit, the nuts are sometimes peeled in warm water, and used as a component in dishes like blanched almonds; or converted into a kind of chocolate; or made into bread; or pressed to yield an oil little inferior to almond oil. The wood of the tree is not large enough for building purposes; but it is used in cabinet-making, and in the manufacture of a number of small articles; it is close, even, and pliant, but does not take a good polish. Some of the roots yield curiously-veined pieces, eagerly sought after for ornamental purposes. The smaller branches and twigs of the hazel are more useful than the main trunk, on account of their toughness and flexibility; they are largely employed for crates, hurdles, props, wattles, walking-sticks, fishing-rods, whip-handles, ties for faggots, springes for birds, thatch-fastenings, &c. Evelyn, among other mention of the uses of this tree, said: "The use of the hazel is for poles, spars, hoops, forks, angling-rods, faggots, cudgels, coals [charcoal], and sprynges to catch birds; and it makes one of the best coals, once used for gunpowder, being very fine and light, till they found alder to be more fit. There is no wood which purifies wine sooner than the chips of hazel. Also, for withes and bands; upon which, I remember, Pliny thinks it a pretty speculation that a wood should be stronger to bind withal, being bruised and divided, than when whole and entire." Hazel-rods, cut of equal size and varnished, form good materials for rustic garden-seats and flower-baskets; and many ornamental devices may be produced by using some peeled, and the rest unpeeled. A laborious but uncommendable attempt has been made to produce a kind of mosaic picture, by interlacing differently-coloured hazel-rods.

A peculiar abuse, rather than a use, of the hazel, is described under Divining-Rod. The old herbalists, too, had singular notions about this plant, which modern medicine has by no means confirmed.

HEAD, INJURIES OF THE. From the many peculiar and important features which they present, injuries of the head have properly received a separate consideration in all systems of surgery. For not only is the brain so essential to life that even its least injury must be regarded as serious, but the parts around and guarding it have many peculiarities. The skull, composed of two thin layers of bone, much exposed to external violence, and protected from it by only slight coverings, is extremely liable to fracture, and it is covered by a very dense and tightly applied membrane, the pericranium, of which the injuries and diseases exhibit all the peculiarities of those of other fibrous membranes. By the free communications of its vessels with those of the similar membrane (the dura mater) lining the interior of the skull, and less directly with those of the brain, disease is very liable to spread from the pericranium to these more important parts; and it is itself covered by firm unyielding muscles and tendons, under which disease is always prone to extend widely. The injuries of the head are best considered as they affect the parts enclosing the brain or the brain itself.

In mere bruises of the scalp two circumstances are worthy of notice. A vessel of some size may be burst without the skin over it being wounded, in which case a most copious effusion of blood takes place, raising up the scalp from the skull, and producing rapid swelling of the whole of the upper part of the head. It needs however no particular treatment; no incision should be made into it, for if cold wet cloths be diligently applied, the blood will be again rapidly absorbed. If the effusion of blood from the bruise takes place between the pericranium and the skull, the former is raised into a tumour, with sharp defined edges, and yielding to pressure in a manner so similar to that of fracture with depression of the skull, that the most experienced surgeon might be deceived and induced to apply the trephine, but for the rule that it should never be employed except in cases in which the brain itself is implicated.

A common superficial wound of the scalp needs no particular treatment. It should be closed with sticking-plaster after the hair around it has been shaved off, and it should be kept cool; but to guard against mischief to the adjacent parts, the patient should avoid all stimuli, and all exertion of either body or mind, till it is completely well. Not unfrequently a violent oblique blow will strip off a large flap of the scalp so as even to denude the bone. In cases of this kind, the part, after being carefully cleaned, should be accurately replaced: if absolutely necessary, a suture may be inserted to ensure more exact adaptation, and the rest should be closed by adhesive-plaster; the head around, being shaved, must be kept perfectly cool; the patient must be placed on low diet, take aperient medicine, and remain quiet; on the first appearance of general excitement blood must be taken from the arm, and by leeches applied round the wound; under this treatment many cases get well with almost singular rapidity; but if irregularities be permitted, serious consequences may ensue even from the slighter injuries.

One of the most common of these sequels of injuries of the scalp is erysipelas of the head and face. It generally occurs in persons of an unhealthy habit, in hard drinkers, and in the full and plethoric. It commences about the third or fourth day after the injury; the patient begins to complain of headache and a feeling of general illness; he has a shivering fit, followed by nausea, thirst, and restlessness; a quick and hard pulse, and a thickly-coated tongue; he cannot sleep, and is perhaps slightly delirious. Soon after these symptoms have commenced the head and face feel very hot, and become red and swollen, appearances which increase, and after a day or two are accompanied with an eruption of small blisters, full of yellow fluid. There is no pain on touching the parts; but by the great swelling the eyes are often closed, and the features almost obliterated. Active reducing measures should, as a general rule, be early employed, and continued, if the disease does not yield, as far as the patient's strength will permit; and purgatives, with small doses of mercury, should be given, for the liver is very generally affected. After a period of from five to eight days the inflammation in most cases subsides, the cuticle scales off, and the wound, which had assumed an indolent unhealthy appearance, acquires a vigorous aspect, and rapidly heals. But in some cases the cellular tissue thus affected suppurates and sloughs, the scalp is separated, and there is profuse discharge from the wound. One or two incisions should in such case be made into the sloughing part, to admit of the free separation of the sloughs; but even with this the disease will sometimes spread and prove fatal.

Another affection which sometimes follows injuries (and especially punctured wounds) of the external coverings of the skull is inflammation and consequent extensive suppuration in the loose tissue connecting the tendon of the muscle covering the top of the head with the pericranium. The general symptoms of fever are in these cases less severe than in erysipelas; the scalp is less hot and swollen, but more painful and very tender; the face is never affected. After a few days of general illness, a feeling indicating a collection of fluid may be perceived over some part of the head; and on making an opening into the swelling which has formed there, a quantity of matter may be pressed out of it from beneath a large portion of the scalp. When this affection is suspected to be coming on, leeches should be put on the head in large numbers about the wound, and cold diligently applied; but if matter should form, one or more free incisions should be made through the scalp to let it out, and the part afterwards treated like a common abscess.

In cases in which the bone has been exposed, the same general and local treatment should be employed. The scalp when replaced may at once unite to the bone; or if it do not, granulations may spring up from the surface of the bone and close the wound: in worse cases, the outermost layer of the skull may die, and require a tedious process for its exfoliation and healing; in the worst, the whole thickness of the skull may perish, and the dura mater be exposed. In all these cases the mildest treatment is requisite, but as the disease is extremely liable to spread to the interior of the skull, the general health should be carefully watched, and if any indications of mischief arise, general or local bleeding should be at once employed.

When the bone itself is injured, no active treatment should ever be adopted, unless there are evident signs that the brain is suffering from compression or any injury that may be mitigated. These fractures of the skull get well even more rapidly than those of other bone; and in some cases, especially in children, the skull may be forced in to some extent, but when it does not produce any derangement of the functions of the brain the injury will be repaired, and health perfectly restored. Cases of fracture of the skull in which the brain is not at first injured may be amongst either the most simple or the most dangerous in surgical practice—for the least intemperance or irregularity committed within some time after their reception may produce irreparable inflammation of the brain or its membranes.

Injuries of the dura mater (the membrane lining the interior of the skull) are of yet more importance, because they more immediately affect the brain. The dura mater is connected with the skull by a tissue in which numerous vessels ramify, and these may be ruptured by the jar from a blow which does not even break the skin. The blood that flows from them, accumulating between the dura mater and the skull, produces compression of the brain. The chief indication of this very dangerous accident having occurred is that the patient, who for some time after the blow had seemed only stunned, or had been even quite sensible, gradually becomes dull, sleepy, comatose, and at last totally insensible, just like one suffering from apoplexy. These symptoms supervene with a rapidity corresponding to the size and number of the vessels ruptured; the most rapid are those in which, by a blow on the side of the head, the main artery, supplying the dura mater and upper part of the skull, and which ascends just before the ear, is wounded. The only hope in these cases is to bleed the patient largely, to check the flow of blood in the head, and if that be not evidently beneficial, to apply the trephine wherever it is most probable that the blood may be found and removed. It must be confessed, however, that there is little prospect of doing good by trephining in these cases; it is seldom possible to decide at what part of the skull the blood is effused, or whether it may not be between the dura mater and the brain, or even in that organ itself. The symptoms in each case are the same, but the mechanical removal of the blood is possible only when the blood is immediately beneath the upper parts of the skull.

Instead of blood, purulent matter may collect between the dura mater and skull, and produce equally fatal results. This is indicated by the patient (usually some considerable time after the accident) complaining of headache, restlessness, and extreme languor; he has frequent irregular shiverings, his pulse is quick and hard, and he cannot sleep: if unrelieved by treatment, all these symptoms increase, and are shortly followed by delirium, convulsions, insensibility, or paralysis, which are no distant precursors of death. Early after their first appearance, a puffy, soft, but not very hot nor painful tumour, forms over the part struck. If this be opened, the pericranium will be found detached for some extent from the skull, which when exposed is seen to be dead, of a dull yellow colour, and covered by purulent fluid. In this case it may be expected that the dura mater is separated from the interior of the skull to the same extent that the pericranium is from its exterior, and the only hope of relieving the patient is to perforate the dead portion of bone with the trephine, and let out the matter collected between it and the dura mater, and which compressed the brain.

The brain itself may suffer injury either from blood effused in it by rupture of its vessels, from compression by fractured portions of bone being forced down upon it, from wounds, from concussion, or from inflammation, and its various effects following any of these injuries. The first need not here be particularly treated of; it does not differ in its symptoms from the cases of common apoplexy with effusion of blood [Apoplexy], and admits of no mechanical treatment. The second class comprehends the most important injuries of the head; those of "fracture with depression," as they are called, and those which occasionally happen in children, in which the skull is indented without being broken. The symptoms of such an injury are insensibility, generally in direct proportion to the degree of pressure; the breathing is slow, laboured, and snoring, and at every expiration the cheeks are puffed out and elevated; the pulse is slow and irregular; the pupil widely dilated and insensible to light; the patient neither feels nor moves, and lies as if in a fatal state of apoplexy. The part struck may of course present most varied characters: it may be *starred* from the centre of the blow, so as to have a shallow conical depression; it may be fissured, and one edge have passed under the other; or it and the scalp may be broken up confusedly, and the brain be protruding through the openings in them. It is worth remembering that the inner part of the skull may, in consequence of its brittleness, be much more widely fractured than the external, so that the degree of pressure on the brain is not always indicated by the depth of the indentation felt in the scalp. If unrelieved by treatment, the patient from the time of the accident grows more and more insensible; his pulse becomes more irregular, and he rapidly dies. The evident and indeed the only mode of affording relief is to remove the pressure from the brain, by exposing the fractured part of the skull by enlarging the wound in the scalp, or making a fresh one, and taking away or elevating all the portions of bone that are depressed. The mode of doing this will be determined in each case by the form of the fracture and other circumstances; in some it may be sufficient to remove the loose pieces with forceps; in others, to saw off portions with a Hey's saw, or to apply the trephine and raise the other depressed parts to their proper level with an elevator. These proceedings however must of course be limited to the cases in which the fracture is in a part within view; when it extends across the base of the skull no mechanical means are applicable, and recovery is therefore extremely rare. Such cases, and all others in which compression cannot be mechanically relieved, can only be treated like common apoplexy, by bleeding the patient, by cold sedulously applied, and by rigorous reducing measures. The after-treatment of cases in which the trephine or analogous means have been used is nearly the same as in wounds of the skull and soft parts; the edges should be brought gently together, and slight pressure employed to support the dura mater where it is exposed by the aperture in the skull: and the other usual precautionary and curative measures, as cold, local bleeding, &c., resorted to.

The immediate consequences of wounds of the brain vary greatly, and indeed unaccountably: in some cases a very slight injury is rapidly fatal, as in those (of which many are now recorded) in which a pointed instrument has passed in through the orbit, and produced almost instant death; whilst in others severe and extensive injuries, as from gun-shots, have been followed by serious symptoms at only a late period from their reception. In most of the cases where the dura mater is perforated, whether by wound or by ulceration, the wounded or exposed brain protrudes through the aperture in the form of a darkish dirty-looking fungous mass, called "Hernia Cerebri." Its surface discharges purulent matter abundantly, and often bleeds slightly: pressure on it, as on the brain itself, produces immediate insensibility; but the whole mass may be cut off without producing any pain or ill consequences. This is indeed the best treatment of it. If after having protruded to some distance it shows no disposition to decrease or to slough, it should be cut down to the level of the skull, and gentle pressure by compresses covered with the mildest ointment applied, so as to compensate, if possible, for the deficiency in the dura mater. Should the mass again sprout forth, the same treatment may be repeated. In a few cases the growth is checked, and the brain produces healthy granulations, which unite to the surrounding parts and skin over; in others the fungous mass sloughs and the remaining parts heal; but in the large majority the exposure of the brain and its irritation by surrounding parts produce such continued inflammation of it as proves fatal.

The last injury of the brain that needs particular notice is that called concussion or commotion. The exact nature of it is totally unknown; the name indicates only that which has been supposed, namely, a shaking or general disturbance of the minute parts of the brain. In its slightest degree it is merely a stunning, from which perfect recovery takes place in a few minutes; in its most severe, it is rapidly fatal; but even in these, a post-mortem examination discovers no alteration whatever in the structure of the brain. One of the most interesting points in surgery is the diagnosis of concussion from compression of the brain. As the latter seldom occurs without the former (for of course a blow which would fracture or indent the skull would violently shake the brain), compression has the symptoms of concussion, with the addition of some of the most severe which we have already mentioned. In concussion the patient is insensible only to slight impressions, for if he be loudly called to, he will wake up, answer a word or two, perhaps even rationally, and then relapse into the same state. If he be severely pinched or otherwise irritated he will withdraw the part so injured: he occasionally moves his limbs; he appears, in short, as if in a sound heavy sleep, like that of a drunken man. The breathing is not stertorous, but generally quite natural; the pupil is contracted and irritable; the pulse is sometimes unaffected, but in severe cases small and weak; there is nausea or vomiting, and the extremities feel cold. If the case is about to terminate fatally, the whole body grows rapidly cold, the pulse becomes irregular and weaker, the breathing short and interrupted, and the insensibility increases. In treating cases of concussion much caution is needed: it has not appeared that bleeding, which is the remedy popularly expected for all such accidents, has at all diminished its primary symptoms, nor has the contrary treatment by stimulants been more successful. The patient, while suffering from the immediate stunning consequences of the blow, should merely be kept quite warm in bed, and carefully watched; if the pulse grow weaker, the extremities colder, and the other symptoms of sinking seem increasing, stimulants are first called for, and should be given till he is completely roused to his former state; but if, instead of being depressed, he remain stationary, no active means of any kind should be employed. Cases are not rare in which, after remaining in a nearly insensible state, as if in a sound sleep, for four, six, or eight weeks, with only very slight temporary alterations, the patient wakes, complaining of but little inconvenience, and rapidly recovers. If instead of waking nearly well, he is observed to grow restless, to seem suffering from headache, or should he be delirious or convulsed—if his pulse becomes quick and hard, and his eyes are hurt by strong light—he has in all probability inflammation of the brain, which is the most frequent consequence of concussion, and must be at once met by the active depleting and reducing measures necessary for its cure, from whatever cause it may arise. In some cases the symptoms of concussion gradually change into those of compression, which may then be suspected to arise from effusion of blood into or on the brain, as in the cases already mentioned.

The account here given is only a sketch of the most prominent and constant symptoms, progress, and treatment of the effects of injuries of the head. There are other symptoms that occur occasionally, and as it were accidentally, which it is necessary briefly to advert to. Furious delirium, lasting for some days and requiring active depletion, sometimes immediately follows concussion; violent convulsions also ensue, either on slight compression or on concussion; paralysis or hemiplegia is not unfrequently produced directly by compression, and they still more commonly occur as its sequels. Loss of memory, sometimes most singularly limited to particular classes of events or things; impairment of individual sensations, and various forms of insanity, are all the occasional consequences of these injuries, or of the inflammation and disorganisation of the brain which follow them, and to the prevention or cure of which the chief attention is, in the majority of cases, to be directed.

HEADBOROUGH. [Constable.]

HEALTH. [Public Health.]

HEARING TRUMPET. [Ear-Trumpet; Speaking-Trumpet.]

HEARSAY. [Evidence.]

HEART, DISEASES OF THE. The heart, like the other viscera, is concealed from the eye, hence little knowledge of its healthy or diseased conditions can be obtained by mere inspection. Even the touch fails to ascertain much, on account of the bony case in which it is enclosed. Its impulse may, however, be detected by grasping the chest with the hand. The arterial pulse may be also felt by the finger, but these means of examination give but little information of the nature of diseases of the heart, compared with the use of the ear. Disease of the heart can be detected both by the aid of auscultation and percussion.

When the ear is applied to the left side of the chest, either directly or with the aid of the stethoscope, two sounds are heard, called the first and second sounds of the heart. [Heart, in Nat. Hist. Div.] The two sounds differ from each other, and the period of silence between the two sounds also differs. The first sound is longer than the second, and the two have been compared to the syllables *lupp* and *dupp*. It is heard most distinctly below and outside the left nipple, and with the systole of the ventricles, and on these accounts is called the *systolic* or *inferior* sound. The second sound is heard above and inside the left nipple, and is called the *superior* sound. It occurs with the diastole of the ventricles, and is called the diastolic sound.

The pause between these two sounds differs in the length of time it occupies: after the first sound and before the second it is *shorter* than between the second and the first.

These sounds present different characters in different individuals in health, and even in the same individuals at different times. They, however, indicate disease when they are permanently altered from their normal character. Thus they may be lower or higher, clearer or duller, muffled, rough, regular, irregular, intermittent, increased or decreased in number. Their quality may be altered, and they may be accompanied by friction sounds from disease of the pericardium, or murmurs may ensue from disease of the valves, as bellows, grating, filing, rasping, cooing, or whistling murmurs. There is also a relation between the sounds of the heart and the pulse. The first sound in health anticipates very shortly, but still very distinctly, the pulse at the wrist, hence any prolongation of this period is indicative of some obstruction to the course of the blood.

A knowledge of the nature and causes of the murmurs and abnormal sounds produced in the heart is essential to a correct diagnosis of diseases of the heart. These murmurs or morbid sounds may arise from disease within the heart, when they are called *endocardial*; or between the heart and its lining membrane, the pericardium, when they are called *exocardial*. The two classes of murmurs may co-exist. The endocardial murmurs arise either from an unnatural contraction or an unnatural widening of the orifices between the vessels and cavities of the heart. They may also arise from states of the blood. When caused by the latter they are called *functional* or *inorganic*, but when from the former *organic*. The exocardial murmurs arise from the roughening of the surfaces of the heart and pericardium.

Each of the orifices of the heart may be the seat of two different kinds of murmurs, the one constrictive, the other regurgitant; the one occurring *with* the current of the blood, the other *against* the current. In this way eight different kinds of murmurs are recognised. It should, however, be remembered that the murmurs on the left side more frequently occur than murmurs on the right side. The following account of these murmurs, given in the order of their frequency, will give an idea of their character and the means of distinguishing them.

1. *Mitral regurgitant murmur.*—This arises from inefficiency of the mitral valve by changes in its structure, roughness at its edges, from vegetatious shortening of the *chordæ tendineæ*, or fibrinious clots entangled in them. It is a systolic murmur, and is heard best immediately above or to the outside of the left apex. It is faintly or wholly inaudible at the right apex. It is generally permanent.

2. The *Aortic constrictive murmur* is the next most frequent abnormal sound in diseases of the heart. It indicates a rough constriction of the aortic orifice. It is a systolic murmur, and is heard best at mid-sternum opposite the interspace, between the third and fourth ribs, or the upper part of the fourth rib. It has a high pitch, and is a harsh, loud, and prolonged murmur.

3. *Aortic regurgitant murmur.*—It differs from the last in being heard almost as distinctly at the ensiform cartilage as at the third costal interspace. It is a diastolic murmur, and is of a blowing or hissing character.

4. *Mitral constrictive murmur.*—It is diastolic, and heard best immediately above and about the left apex.

5. *Tricuspid regurgitant murmur.*—It is due to regurgitation, or to the collision of the blood amongst the *chordæ tendineæ*. It is a systolic murmur, and is heard best immediately above or at the ensiform cartilage. It is inaudible, or nearly so, at the left apex. It originates in the right ventricle, and is generally a soft murmur of low pitch. It is a rare murmur, and may be often undiscovered when accompanied by a powerful mitral murmur.

6. *Pulmonary constrictive murmur.*—It indicates roughness, or obstruction from pressure in the pulmonary orifice. It is a systolic murmur, and is heard best at the sternal edge of the third left cartilage. It is rarely heard.

7. *Pulmonary regurgitant murmur.*—This indication of insufficiency of the pulmonary valves is very rare.

8. *Tricuspid constrictive murmur.*—It is the rarest of murmurs, is diastolic, and when heard is found at the ensiform cartilage.

The exocardial murmurs are produced by the rubbing of the surface of the pericardum against the heart, when these surfaces are roughened by the effusion of fibrine from inflammatory disease. They are more or less rough according to circumstances, and may entirely cease by the effusion of serum or fluid between the pericardium and the heart.

Percussion may be employed in distinguishing enlargement of the heart. It is employed either mediately or directly. [PERCUSSION.] In the normal condition of the thorax, the situation of the heart is easily distinguished by the dull sound given out on percussion. When this dull sound extends unnaturally in any direction over the region of the heart it is indicative of an enlargement of that organ, a condition which will be made evident by other signs of disease.

In giving some account of the disorders to which the heart is liable, it would perhaps be best to arrange them according to their causes; but as it is much easier to obtain a knowledge of the structure of this organ than of the remote causes of its several diseases, we shall here enumerate and describe, first, those lesions which occur in its investing membrane; secondly, those which affect it as a whole; and thirdly, those met with in its internal membranes. Those who desire to be further acquainted with this subject are referred to the works of MM. Corvisart, Laennec, Cruveilhier, Bouillaud, Bertin, and Drs. Elliotson, Hope, Watson, Latham, Taylor, Walshe, Williams, Billing, and Aitken.

I. *Diseases of the Investing Membrane of the Heart.*

Pericarditis, Inflammation of the Pericardium, resembles much, in its pathological conditions, inflammation of other serous membranes, and is induced by similar causes, as exposure to damp and cold. It of course presents peculiar symptoms, arising from the situation and nature of the individual organ: thus the patient will complain of tenderness over the region of the heart, amounting, when pressure is made, to acute lancinating pain, which prevents him from lying on the left side, and is much increased by drawing deep inspirations or coughing,—this latter symptom frequently depending on the pleura being involved in the inflammatory attack. This pain, however, is not always so severe; frequently only a sense of oppression is felt. The pulsations of the heart are frequent, sometimes regular, but at other times intermittent, and so strong as to constitute palpitations; but still, if much effusion has taken place into the pericardium, the hand when applied to the chest will have difficulty in perceiving them. The præcordial portion of the thorax is often bulged out by the forcible action of the heart and the quantity of fluid effused into the cavity of the pericardium. This effusion varies much in quantity and consistence at different periods of the disease: thus, in many cases, only a little bloody serum will be found; in others, pus in large quantities, coagulated lymph, bands of fibrinous matter uniting the two layers of the serous membrane, and even cartilaginous or osseous deposits. The dull sound discovered by percussion in the præcordial region of a person in health is always, in this disease, increased in proportion to the quantity of fluid in the pericardium. In proportion as this fluid becomes organised sounds will be heard by the application of the stethoscope, and often of the unassisted ear, varying in their nature according to the state of the organising process, and resembling at one time the creaking of new leather, at another the rubbing together of paper or parchment, the noise made by a file, &c. Other sounds also are frequently heard, which depend upon endocardial disease. Although at the commencement of the disease the patient may have symptoms of acute inflammation, the accompanying fever having a type sufficiently tonic, this state does not endure long; the effusions into the pericardium hinder the heart's action; the free passage of the blood through its cavities becomes further impeded by various internal parts of the organ sharing in the inflammation; and, the circulation being no longer vigorously and equally carried on, a crowd of distressing symptoms, such as inability to sleep, startings, faintness, shortness of breath amounting to suffocation, dropsies, &c., render life almost insupportable, and, if not speedily relieved, soon put an end to existence. This disease mostly accompanies acute rheumatism, particularly of the joints; and patients, when apparently recovering from acute rheumatism, are sometimes suddenly attacked and carried off by inflammation of the pericardium.

The serious nature of this disease, and the rapidity of its progress, demand, apparently, prompt antiphlogistic treatment; but, on the contrary, some physicians exhibit tonic medicines. Dr. Watson says, "In a large proportion of cases, whether they be treated well or ill, or not treated at all, the patients will seem to recover."

The great guide to treatment is the pressure of the symptoms. At the commencement of the disease, if there is dyspnœa and tumultuous action of the heart, bleeding will immediately relieve. Towards the termination of the disease such symptoms are relieved by wine and stimulants; otherwise the general treatment for rheumatism is admissible in cases of pericarditis.

II. *Diseases of the Heart itself.*

Carditis; Inflammation of the Heart.—The proper muscular structure of the heart is not free from the attacks of inflammation, though whether the morbid action commences in this structure, or in the membranes, is difficult to determine. This, however, is certain, that when inflammation of the muscular structure exists, there will also be found traces of it in the pericardium, or in the lining membrane of the heart, or in both; and we cannot point out symptoms which distinguish the one from those of the other disease: the treatment consequently, will be similar in both.

Hypertrophy of the Heart.—Independently of any morbid process existing in itself, the muscular structure of the heart is often greatly increased in bulk, as if the nutritive process were too active in proportion to the absorbent, and new matter were deposited more rapidly than the old could be removed. From the peculiar nature of the functions of the heart, this disease becomes very important, and its effects not less dangerous than manifold. It is usually divided into three kinds; namely, simple hypertrophy, the least common, in which the parietes are thickened without any change of capacity in the cavity; excentric or aneurismal hypertrophy, the form most frequently met with, in which the parietes are thickened and the inclosed cavity or cavities proportionally enlarged; and concentric hypertrophy, where the cavity is diminished in proportion to the thickness of the parietes. Any one of these kinds of hypertrophy may affect the parietes of either cavity of the heart, or of the whole organ. The extent to which this increase of size may proceed is enormous; hearts have been found weighing upwards of twenty ounces, whereas the average weight of a healthy heart is from seven to nine ounces. In hypertrophy, the shape of the heart is also much altered, the transverse often exceeding the vertical diameter; but these changes must depend upon whether the whole organ, or only a part, be implicated in the disease. The chest is often bulged out towards the left side, the sound produced by percussion more dull than in the healthy state, and the pulsations very strong; indeed, the bed-clothes are often visibly raised, and the head or hand of the observer when applied to the chest forcibly repulsed, yet the pulsations are for the most part regular, unless palpitations be induced by over-exertion. The sounds perceived by auscultation will be found very loud, but not otherwise unnatural, if the disease be not combined with some obstruction to the passage of the blood; and unless some obstruction exists, the functions of other organs will not be much deranged, provided that the hypertrophy be not of great extent; but it seldom does exist to considerable extent without the simultaneous occurrence of some impediment to the passage of the blood, already circulating with extraordinary force.

The accidents referrible to hypertrophy of the left ventricle of the heart are apoplexy and hæmorrhages; it will also contribute to the production of aneurism of the aorta. It frequently happens that the rupture of vessels in the brain by the too forcible expulsion of blood from an hypertrophied left ventricle is materially facilitated by an earthy or osseous state of the coats of those vessels. When the right ventricle, being hypertrophied, sends its blood too forcibly through the lungs, there will be a disposition to congestion of those organs. These effects will be combined when the whole heart is hypertrophied.

This is a disease in which great perseverance is required on the part of the patient and the practitioner, but with proper care it frequently admits of much alleviation. Rest, abstinence, sedative medicines, and more or less depletion, according to the circumstances of the case, are the most efficacious plan of treatment.

Atrophy of the Heart is a wasting of the heart's structure, dependent on deficiency of the nutritive process. This disease is the reverse of hypertrophy, and, like it, may affect the whole organ or only parts of it; its extent is often such that the heart does not exhibit more than half its ordinary weight. Like hypertrophy, it has been divided into simple atrophy, when the walls of one or more cavities are thinned without any change of capacity in the cavity itself; excentric or aneurismal atrophy, when the enlargement of the cavity keeps pace with the thinness of the walls; and concentric atrophy, where the cavity is diminished, but the walls maintain their usual thickness. This state of the heart is usually accompanied by general emaciation, and the pulsations and sounds of the organ will be found feeble in proportion to the extent of the atrophy. In concentric atrophy, however, the pulse will be firm and resistant, though small, whilst in the excentric form of the disease it will be proportionally soft, feeble, and large.

When the heart is examined after death from atrophy, it is found that its tissues have undergone a change which has been called "fatty degeneration." The muscular fibre, instead of presenting the striped character found in health, loses the stripes, and presents a homogeneous appearance. In the interior of the fibrillæ will be found also fat globules, and the central portion of the muscle-cells, consisting naturally of fibrine, is converted into adipocire or cholesterine. It is in this state of the heart that rupture of its membranes so frequently occurs. (Quain, 'Fatty Diseases of the Heart.')

In atrophy the powers of the patient are all below par, and the proper treatment will be to support the system by wholesome, generous, but unexciting diet, and a salubrious atmosphere. Medicines, as quinine and iron, may be prescribed as auxiliaries, when any additional symptoms appear indicating obstruction to the nutritive functions.

Dilatation of the Heart.—It has been shown that the heart may be increased or diminished in substance, or, in other words, may be hypertrophied or atrophied; it is also found that the whole organ, or either of its cavities singly, or the orifices of these cavities, may be dilated, the solid parietes being merely extended, without any increase of substance, and the contained cavities proportionally enlarged. As in hypertrophy, so in this disease, according to its extent, the shape of the heart will be much changed. The muscular parietes being thinned and feeble, the circulation of the blood will not be carried on with vigour, and the patient will be weak and unfit for exertion, easily exhausted by small losses of blood, and sometimes carried off by what under ordinary circumstances would be deemed a trifling hæmorrhage. Partial dilatations sometimes occur after carditis; the muscular structure being thinned at some spot by ulceration, the parietes give way, and form a dilated aneurismal pouch. This disease, though it doubtless does sometimes occur in persons of relaxed muscular fibre without any pre-existing impediment to the circulation, is most frequently the consequence of some obstruction to the free passage of the blood from the dilated cavity, and is the natural effect of distension from within. It however not unfrequently happens, that when the obstruction occurs at the orifice situated between the ventricle and artery the corresponding auricle will be the cavity dilated, its parietes being so much less strong than those of the ventricle. When the orifice of either of the cavities of the heart is dilated to such extent as to preclude its proper closure by the valves, a reflux of blood will be the result, causing the anormal bellows sound, and a sensation of purring, or of vibration such as would be produced by putting a chord in motion; and should this defective closure exist in the right auriculo-ventricular opening, it will give rise to a fluctuating motion in the jugular vein, called "venous pulse." Excessive exertions and strong passions seem to be exciting causes of this disease, and from the influence of these causes the patient should be sedulously guarded, and at the same time every remedy must be adopted which may contribute to equalise the circulation.

The preceding diseases are most frequently the result of disease of the lining membrane of the heart, and are often accompanied by the signs of valvular derangement.

III. *Diseases of the Internal Membranes.*

Endocarditis; Inflammation of the interior lining membrane of the Heart.—The symptoms of endocarditis are more or less fever and anxiety; some bulging of the præcordial region, if accompanied by pericarditis; an extension of the dull sound heard on percussion in the healthy state; the pulsations of the heart unusually strong, and sometimes very rapid and intermittent, repulsing the hand when applied to the chest, and producing a peculiar vibratory sensation. Upon auscultation the bellows sound will be heard, masking one or both of the normal sounds, and sometimes, during the ventricular contraction, a metallic tingling is heard, resembling the sound produced by dropping sand into a bell of metal. The pulse as felt at the wrist will not always accord with the beatings of the heart; often whilst the latter are very forcible, the former will be found small and weak, and sometimes less frequent: this indicates some obstruction to the free passage of the blood from the heart, notwithstanding the forcible contractions of that organ to propel it, and the patient will exhibit symptoms of much distress, as great anxiety of countenance, restless tossings of the body, dazzlings of the sight, and faintings; if the obstructions in the right side of the heart are extensive, as they often are from fibrinous concretions, thickenings, and other morbid growths of the valves, the venous circulation will be affected, as indicated by the livid bloated state of the countenance, and serous effusions into the extremities; various apoplectic symptoms seem to be sometimes induced by the same cause. The breathing is not affected generally beyond a sense of oppression, unless a considerable impediment is experienced by the circulation, but then the distress and restlessness of the sufferer is often extreme, accompanied by an inability to lie down, and a state of alarm and wandering amounting almost to delirium.

The causes of this serious malady are similar to the causes of pericarditis, and the treatment should be conducted on the same principles. It frequently arises in the course of an attack of rheumatism, and may or may not be accompanied by pericarditis.

Valvular disease of the Heart.—Upon examination after death from endocarditis, there will often be found, particularly in the right cavities of the heart, and entangled in the muscular fibres, clots or concretions of fibrinous matter, which are not only caused by stagnation of the blood at the time of death, but also by inflammation of the internal lining membrane. This membrane is also often thickened, especially at the valves; and after repeated attacks, or a long chronic attack of endocarditis, the valves will not merely be thickened, but will become the seat of a variety of warty excrescences, or even cartilaginous and osseous formations of considerable size, extending into the cavities of the heart. This ossification is most frequently met with in old persons, and especially those who have been addicted to a too generous mode of living. The morbid sounds produced by these obstructions at the various orifices will resemble those of the bellows, file, or saw, according to the degree of obstruction; and sometimes a triple or quadruple sound will be perceived instead of the two normal sounds. The effects of these obstructions will be sanguineous and serous congestions, oppressions of the breath, apoplectic seizures, and other symptoms of embarrassed circulation.

The treatment of such cases must depend on the nature of the symptoms present. Where anasarca is present, the water may be got rid of by rest and by acting on the bowels and kidneys. Asthma is frequently the result of valvular disease of the heart, and remedies must be applied to facilitate the passage of the blood through the obstructed lungs. Hæmorrhage from the lungs and extravasation of blood are produced by disease of the heart. Congestion of the brain and apoplexy are also the result of disease of the heart, and it is of the greatest consequence to detect the cause of these attacks in the state of the heart, and adopt treatment accordingly.

Nervous Diseases of the Heart.—The last class of diseases affecting the heart which remains to be noticed differs from all the preceding in not presenting any organic changes. They are met with chiefly in women suffering from anæmia, chlorosis, hysteria, and other nervous symptoms; and in men in whom a naturally nervous temperament has been rendered more irritable by the too free use of stimuli or by depressing passions. In these cases strong pulsations of the heart are experienced, increased by exertion to such an extent as to produce palpitations, a sense of faintness, and shortness of breath amounting to suffocation. Sometimes a loud bellows sound is heard at the heart, and in patients labouring under anæmia and chlorosis this is frequently accompanied by a noise like snoring, heard chiefly in the carotid and crural arteries. In all these cases great attention should be paid to the general health: in the cases of anæmia and hysteria, iron medicines and the shower-bath will be of the greatest service; and, as far as possible, sources of anxiety should be removed. The morbid sounds will all disappear as the mind and body of the patient are restored to their healthy condition, but it must be borne in mind that the heart is essentially a muscular organ, and by severe exercise it may be increased in bulk like other muscles; consequently if these nervous states which give rise to so much action of the heart be not removed, they may in process of time lay the foundation for more permanent and serious disease.

Malformation of the Heart.—Cases of permanent malformation of the heart are few. The only one demanding attention here is the permanent *foramen ovale.* [CYANOSIS.]

HEAT. This great natural agent, which is universally diffused, becomes sensible to us in the first instance by our bodily sensations, but we find afterwards its effects in the various changes which it is capable of producing on all substances. Expansion, fusion, evaporation, thermo-electric currents, and various physiological phenomena, are effects of heat, or at least accompany its absorption.

Every existing substance may be regarded as a source of heat. In this respect the sun is the most important natural source which our system possesses, its heat when condensed in the focus of a lens being exceedingly intense. When concentrated by a number of powerful lenses on one scale of a balance of extreme sensibility, no derangement of equilibrium ensues; as far therefore as experiment can inform us it is imponderable, and the increase or diminution of heat in any body is therefore unaccompanied by any alteration of weight.

Heat may be produced artificially by any means which propagate agitations internally in bodies: hence *friction*, *percussion*, sudden *condensation*, *chemical combination*, including *combustion* and *respiration*, and *electrical discharges*, are all proper to produce or rather to develope heat. Pouillet has also shown that the act of moistening any dry substance produces a rise in temperature of from ½° to 2° in dry mineral substances in powder, and from 2° to 10° or 11° in certain animal and vegetable substances, such as cotton, hair, wool, paper, &c.

As to the nature of heat, whether it should be regarded as a substance or an accident, has been discussed from the time of Bacon to the present day. Those who regard it as having a material existence, suppose that a subtle fluid, called *caloric*, capable of permeating the densest substances, is universally diffused; that its parts are mutually repulsive, but are attracted by the material particles of bodies, and hence they account for the expansions and contractions of bodies, while the effects of radiant heat are explained on principles analogous to those on which the undulatory theory of light is founded.

Those who regard heat as only accidental to matter, rest their opinion on the fact, that the artificial production of heat is accompanied by vibratory motions in the material molecules of the heated substances. The measure of the quantity of heat produced mechanically would on this hypothesis have a direct connection with the sum of the *vis viva* of the system of vibrating particles. Hence the communication of heat by contact would be the same as the propagation of vibratory motions from the system of particles composing the heated body to that of the touching body. This hypothesis is liable to a great objection; for heat is propagated through a vacuum, and if even we suppose all space filled with some fluid, in order to explain solar radiation, the hypothesis loses its simplicity, and differs from the former principally by its greater vagueness. It has been suggested by Brewster, that the solar rays are nothing more than heated light, but this opinion is open to several objections founded on the different laws by which heat and light are transmitted and modified.

It is of greater advantage to study the properties of heat, and make those properties the ground for its measurement and the calculation of its effects, than to speculate on the nature of an agent intimately connected, not only with light and electricity, but with the absolute nature of the material molecules.

Heat radiates from all bodies in straight lines and in all directions, and in the law of its emanation it resembles light, its intensity diminishing in the same proportion as the sine of the angle of emanation. If we conceive two balls which are heated unequally to be enclosed by a concave surface which by any means is preserved at a uniform temperature, the radiation of heat from the warmer ball, directed on the colder, being more copious than the radiation from the latter on the former, the temperature of the hotter will sink, and of the cooler rise, in proportion to the difference of radiations, and this will continue until the temperatures become permanent, in which case the radiations are necessarily equal. In the same manner, when the different parts of a room in which there are one or several sources of heat have acquired a permanent temperature, that temperature for each part will then be such that the heat which it emits by radiation must be equal to the quantity absorbed, and which it has received by radiation from all other parts of the room.

One consequence of the free radiation of heat in open space is, that its intensity must vary inversely as the square of the distance from the origin. Hence every portion of space has a determinate temperature due to the amount of radiation, not only from the sun and fixed stars, but also of the non-luminous bodies of each system. It seems however difficult to conceive with Poisson, that in addition to such temperature from heat emitted, it can have any temperature peculiar to its locality; in fact, that vacuum can possibly have any proper heat.

But though the laws of the free emanation of heat and light are similar, those of their transmission through substances are very different. When a metallic body is but a little heated in a fire, we have heat unaccompanied by sensible light; and in the lunar rays the light, though originally transmitted from the sun, arrives at our planet without any sensible heat, even when collected in the focus of a burning-glass. Again, a plate of glass placed before a common fire will intercept the heat until it becomes itself sufficiently heated to radiate. When however the source of heat is more intense, a small portion will be directly transmitted; while for the solar rays we find the heat is transmitted as well as the light. It is still more remarkable that when the solar rays are decomposed by transmission through a glass prism, the differently coloured rays of the spectrum have each a different intensity of heat, the least refrangible possessing the greatest portion; the greatest heat is found at the place occupied by the extreme red rays, or even a little beyond them.

Not only may radiant heat be collected in a focus by refraction through a lens, but also by reflexion from a polished concave mirror. If we employ a pair of mirrors, and if a heated body be placed in the focus of one, and a thermometer in the other, the reflected heat falling on the bulb of the instrument will cause the mercury to rise; and conversely, a colder body will make the column of mercury descend, for the excess of radiation proceeds in this case from the thermometer. Recent experiments on heat show that the analogy of the laws of heat and light extends even to polarisation.

The experiments of Leslie have shown how greatly the quantity of radiant heat may be affected by the state of surfaces from which it finally emanates. The method adopted by Leslie for examining the powers of radiation possessed by different substances was extremely simple and ingenious. Having employed the system of two specula above mentioned, he placed a tin canister filled with hot water in the focus of one, and a differential thermometer [THERMOMETER] in the other focus. The four sides of the tin canister were covered with the substances of which he proposed to seek the radiating powers; when three of the sides were respectively covered with lamp-black, paper, and crown-glass, and then turned so as to radiate directly on the speculum, the heat reflected by the other speculum raised the thermometer accordingly to 100°, 98°, and 90°; but when the fourth side, which was uncovered, was similarly directed, the thermometer fell 12°. Thus it appears that polished metallic substances are bad radiators, which may be attributed to the internal reflexion of the heat from their surfaces, for the sources of radiation must evidently be at some small depth below the geometrical surfaces. A similar apparatus served to measure the absorptive power of different substances, by covering the bulb of the thermometer as uniformly as possible with an envelope of the substance to be examined; this power was thus found to be nearly in proportion to that of radiation. The maximum effect of the reflected heat was not however in the strict geometric focus, but, in consequence of aberration, it was found to be a little beyond it. At a later period Ritchie contrived a species of differential thermometer from which, by direct experiment, he was enabled to prove that the power of radiation from any surface is exactly equal to that of absorption at the same surface. A hollow air-tight cylinder of tin, having one half of its exterior surface bright and the other covered with lamp-black, was fixed in a vertical position at each extremity of a bent glass tube containing a coloured spirit; and midway between these was placed a vessel similar to the others, and like them coated on half its surface. When the instrument was to be used, the middle vessel was filled with boiling water; then the bright side of one of the first-mentioned cylinders being turned towards the coated side of that which contained the water, while the coated side of the other was turned towards the bright side of the latter, the rarefaction of the air within the cylinders at the extremities of the tube, in consequence of the heat absorbed by them, was proved to be equal by the coloured spirit remaining stationary in the tube. ('Journal of the Royal Inst.,' December, 1831.) It is evident, here, that if the quantity of heat which radiated from the bright side of the middle cylinder were represented by $\frac{1}{n}$th of that which issued from the coated side; the bright side of the cylinder at one extremity of the tube absorbed $\frac{1}{n}$th of the latter quantity while the coated side of the cylinder at the other extremity absorbed all the former, that is, an equal quantity.

The power of radiating heat is certainly the most universal mode of its propagation between different particles of matter as well as through considerable spaces. However, it is usual, for greater simplicity, to designate this propagation through solid bodies as *propagation of heat by contact.* Poisson has shown in his memoirs on that subject, that the general equations which express the law of the distribution of heat in solids may be derived from the internal radiation of the particles which compose them. Whichever of these two views may be adopted, we are led to important physical distinctions between different homogeneous substances, viz. their conducting powers internally and externally. If we take two substances, as a piece of metal and of wood, at the same temperature as indicated by the thermometer, when held in the warm hand the metal will feel colder than the wood, the heat of the hand being more rapidly absorbed by the metal, as being the better *conductor* of heat. Or if we place the extremities of a rod of copper and of glass in a fire, and hold with the hands the other extremities, the heat will be found to ascend rapidly through the metal and very slowly through the glass rod. Though such plain observations are sufficient to give a general idea that bodies conduct heat differently, yet, to obtain exact measurements of conducting powers, it will be necessary to have a more precise idea, since such power is a constant coefficient belonging to every body in particular, and without the knowledge of which it would be impossible to compare the result of theory with observation.

Newton remarked that, when two substances of unequal temperatures were placed in contact, the colder received from the other in a given small time a quantity of heat proportional to the difference of their temperatures. This simple law has been found to be not strictly correct, but is sufficiently so when the difference of temperatures is inconsiderable. If t t' represent the temperatures of two bodies of the same physical nature placed in contact, and if we leave out of consideration the heat escaping by radiation from their surfaces, the quantity of heat communicated may, by Newton's law, be represented by $h\,(t-t')$; where the coefficient h is a constant peculiar to the given substance, and is proportional to the interior conductibility.

If now we conceive the surface of the body to be of a uniform temperature, and subject to a current of air also of a uniform but inferior temperature T, the loss of heat by a unit of surface in a unit of time indefinitely small will, by the same law, be represented by $H\,(t-T)$, where the coefficient H is proportional to the exterior conductibility under such circumstances.

The exterior conductibility may be very different in the same body by slight alterations in the smoothness or even colour of the surface; it is by this antagonist principle that heat acquires a permanent state corresponding to the different positions of the parts of bodies relative to the sources of heat and the dispersing surfaces.

The mathematical theory of the distribution of heat is founded on the principle that when a body has arrived at a permanent state of temperature the quantity of heat given out by any particle to the adjacent colder region must be equal to that received from the warmer particles near it, and conversely. For example, suppose a solid body to be contained by two parallel planes of indefinite extent, the lower plane being preserved by any means at a uniform temperature represented by 0, and the upper likewise preserved at a uniform temperature. In this case it is easily seen that the temperature would be uniform in any section of the body parallel to its bases, but would increase from the lower plane in an arithmetical progression to the upper, for with this law the temperature of any point of the body taken in the transverse direction will differ by equal quantities from the temperatures of any two points which are at equal distances, the one above and the other below it; hence the flux of heat from the warmer region to this point is equal to that from this point to the colder. Though there is therefore a constant flux of heat from the upper to the lower plane, the distribution of heat has then acquired a permanency.

In the above instance we have had no regard to the external conductibility through the sides by supposing the planes of indefinite extent. A simple instance will now be adduced in which we can show the manner in which this consideration may be introduced into the calculus.

Suppose a thin cylindrical rod to be placed in a medium of which the temperature is constantly zero, while its extremities are maintained at constant but different temperatures. In this case the distribution of heat will follow, at equal distances along the rod, a geometrical progression, increasing from the colder extremity to the hotter; for on this supposition the heat which would be retained by any section in consequence of the unequal differences of its temperature with those of sections similarly placed above and below it, if there were no radiation, will be exactly lost by the external means of conduction, for it is a property of the terms of a geometrical progression that the second differences are proportional to the terms themselves; the heat which would be retained is proportional to this second difference, and the heat externally emitted is proportional to the temperature itself. Thus this law, which renders the internal gain of heat equal to its loss externally, represents the law of its permanent distribution. Those who are acquainted with the calculus of partial differences may find these principles applied, not only to the permanent distribution of heat, but to the laws of cooling in bodies warmed from any sources, and bounded by any surfaces, in the excellent work of Fourier (*Théorie de Chaleur*), and in the memoirs of Poisson, Libri, and others.

The propagation of heat in liquids depends very little on any communication by contact. If we place a heated plate on the surface of water in a vessel, but so as not to touch the edges, a thermometer placed in the water will indicate little or no alteration of temperature; liquids are therefore heated by the transposition of their parts, or by *convection* as it is called. Thus, if with a blowpipe we apply heat to the bottom of a vessel containing water, in which are floating some small particles of dust, a current will be perceived of the warmed liquid rising from the point to which heat has been applied, and another descending current of the colder parts, which being heated in turn rise also; in this manner the heat is distributed through the whole liquid, for as the heat expands the particles of liquid which it first meets, they become specifically lighter than the adjacent fluid, and they must therefore ascend by the laws of hydrostatics, while the heavier take their places.

The experiments which have been made to determine whether liquids are conductors of heat, consist in introducing into a cylindrical vessel half filled with the fluid whose conducting power was to be examined, a quantity of heated fluid of less specific gravity, all due precautions being used to prevent the particles of the two fluids from intermixing; and it was constantly found that thermometers placed at different depths in the former indicated a gradual descent of caloric from the upper to the lower surface. By such experiments Thomson, Dalton, and others, have found that, with equal volumes of the fluids, the conducting power of linseed oil is rather greater than that of water, and the conducting power of mercury about twice as great.

Little as is the conducting power of liquids, that of gases is probably much less, if any; but there would be great difficulty in establishing this experimentally. The effect of heat on gases is to increase proportionally their elasticity, and this disturbing force produces violent motions in their parts, so that the whole shortly acquires a uniform temperature, when other forces, such as gravity, are not taken into consideration, and when the bounding surfaces are not essentially subjected to constant unequal temperatures.

These three modes of the propagation of heat exist in our globe, and are the cause of important phenomena in the distribution of climate.

First the great mass of the earth, considered in reference to its solid parts, has an external source of heat in radiation principally from the sun. The maximum quantity of this heat is bestowed on the region between the tropics, while the poles are at a temperature which, but for the action of the sea and atmosphere, would probably be that of space; the internal heat of the earth would in a homogeneous sphere be distributed symmetrically relative to its centre, diminishing towards the surface, which would lose heat by external radiation; but the external source of heat alluded to, by producing a flux from the equator to the poles, forms a permanent compensation for this radiation.

If we suppose the mass of the earth to have been at any remote period at a very high temperature, of which, besides its general form, there are many striking geological proofs, the effect of the radiation of its heat through the colder surrounding space would be to cool first the superficial strata, and successively, though in a less degree, the internal strata, until a permanent state was reached, when the diminished radiation would be exactly compensated from external sources. Hence, on descending below that comparatively shallow envelope affected with diurnal or annual variations of temperature, we ought to find a continually increasing temperature towards the centre, a result which has been verified in the mines in several countries in Europe. Poisson deems these experiments inconclusive, in consideration of the small depth which we are enabled to penetrate; for without assuming any increase of heat towards the centre, the same superficial phenomenon would occur on the supposition that the whole solar system had been transferred into a region of space possessing a different temperature from that in which it formerly moved; but this view, which is purely speculative, cannot be verified by facts.

The propagation of heat by motion in fluids has a necessary tendency to equalise the temperatures of different latitudes, and the unequal depths of different places in the bed of the sea would, from the same cause, produce currents warmer than the adjacent water. The elasticity acquired by portions of the air in contact with the warmer regions of the globe destroys the equilibrium of that fluid, and generates winds of which the heat is communicated to the districts traversed, while the counter-currents, or cold winds, rush forward to occupy the abandoned spaces. The earth having always had a rotation, a limiting surface necessarily existed beyond which the centrifugal force prevailed; hence if the surface of the earth has ever had a temperature of 212° Fahr., the waters now occupying the bed of the sea, being in a state of vapour, could have filled no more than the space between that limiting surface and the surface of the earth; but the greater cold would necessarily convert the vapour in the upper regions into water, which, descending in rain, would be again vaporised, and this reciprocal action going on during the process of cooling, would be capable of producing immense alterations on the earth's surface. It has been suggested by Mr. Babbage, that a cause of a similar nature may have led to the rings and belts of the superior planets.

Most of the instruments constructed to measure heat are founded on its general tendency to produce expansion, but a few of them on other properties of heat. Besides the various thermometers, we may notice the *calorimeter* of Lavoisier and Laplace, in which an internal chamber of a box is preserved at the temperature of melting ice, being constantly surrounded with that substance, guarded against the contact of the air: in a division of this chamber, a cell furnished with a stop-cock, a body is plunged at any temperature, and remains until it ceases to melt the ice, when the quantity of melted water conducted through the stop-cock is taken as a measure of the quantity of heat given out by the body. This instrument is of use in determining the *specific heats* of substances, and the calculation of *latent heat*. For the measurement of high temperatures, see PYROMETER.

The dilatation of substances by heat is, in general, nearly proportional to the increase of temperature, except when they are about to change their physical or chemical states; thus water near the freezing-point expands when the temperature is diminished, which is probably owing to the different arrangement assumed by its constituent particles preparatory to crystallisation.

The value of the thermometer mainly depends on the assumption that equal increments of heat produce equal amounts of expansion. Still, however, this is not strictly the case; mercury, for example, in the 10° between 30° and 40°, expands less than in the 10° between 200° and 210°, but it fortunately happens, that the increase in the capacity of the glass bulb, especially if the thermometer be made of crown-glass, very nearly compensates for the increasing rate of expansion in mercury. Between the freezing and boiling points of water, the thermometer may therefore be relied on; but above 212° the instrument is not so exact. In general, in all bodies, there is an increasing rate of expansion for increasing temperatures. In the case of mercury, Regnault found that between 32° and 212°, its expansion was 1 in 55·08; between 212° and 392°, making an equal interval, it was 1 in 54·61, and between 392° and 572°, also an equal interval, it was 1 in 54·01. Platinum expands more equably than any other of the metals; but gives a similar increase in the rate of expansion as the temperature rises. According to Dulong and Petit the increase in dilatation of the following substances is the result of experiment:—

Materials employed.	Between 32° and 212°.	Between 32° and 292°.	Between 32° and 572°.
Glass	1 in 69660	1 in 65340	1 in 59220
Platinum	1 in 67860		1 in 65340
Iron	1 in 50760		1 in 40860
Copper	1 in 34920		1 in 31860
Mercury	1 in 9990	1 in 9665	1 in 9518
" (Regnault) . .	1 in 9915·7	1 in 9776	1 in 9647·6
" in glass . .	1 in 11664	1 in 11480	1 in 11372

Regnault further found that the dilatation of mercury between 32° and 662° was 1 in 9582·7. At high temperatures air is more reliable than mercury. The temperature of 572°, as measured by an air-thermometer would, if measured by a mercurial thermometer be 586°. In gases, and also in vapours considerably above their points of condensation, the expansion is the same in all under similar variations of air and pressure, and in general it may be stated that from the freezing to the boiling point of water they increase in bulk more than one-third, 1000 parts at 32° becoming 1366 at 212°. Rigid inquiry, however, by such observers as Regnault and Magnus, show that the co-efficient of expansion is not strictly uniform for all aëriform bodies: the expansion is greater for those which are most readily condensable, but most uniform for gases which have not been liquefied. Practically, however, there is but little chance of error in the statement that gases and vapours between 32° and 212° expand by heat $\frac{11}{30}$ths of the volume at 32°, or about $\frac{1}{409}$ for each degree of Fahrenheit.

It was noticed by Mitscherlich that doubly refracting crystals under the influence of heat expand unequally in different directions. A crystal of calcareous spar, for example, when raised from 32° to 212°, elongates most in the direction of the optic axis, and contracts in directions at right angles to this. As in the case of liquids, solids expand unequally for equal additions of heat; zinc expanding much more than iron, and iron more than glass. The total expansion of a body may be obtained very nearly by multiplying the linear expansion by 3. The following table gives the expansion in length and in bulk of certain solids between 32° and 212°:—

1·000,000 Parts at 32° Fahr.	Become at 212° Fahr.	EXPANSIONS.		Authorities.
		In Length.	In Bulk.	
English flint-glass .	1·000,811	1 in 1248	1 in 416	Lavoisier and Laplace.
Glass tube (French)	1·000,861	1 in 1148	1 in 382	Dulong and Petit.
Platinum . .	1·000,884	1 in 1131	1 in 377	
Palladium . .	1·001,000	1 in 1000	1 in 333	Wollaston.
Tempered steel .	1·001,079	1 in 926	1 in 309	Lavoisier and Laplace.
Antimony . . .	1·001,083	1 in 923	1 in 307	Smeaton.
Iron . . .	1·001,182	1 in 846	1 in 282	Dulong and Petit.
Bismuth . . .	1·001,392	1 in 718	1 in 239	Smeaton.
Gold . . .	1·001,466	1 in 682	1 in 227	Lavoisier and Laplace.
Copper . . .	1·001,718	1 in 582	1 in 194	
Brass . . .	1·001,866	1 in 536	1 in 179	
. . .	1·001,909	1 in 524	1 in 175	
. .	1·001,937	1 in 516	1 in 172	
Lead . . .	1·002,848	1 in 351	1 in 117	
Zinc . . .	1·002,942	1 in 340	1 in 113	Smeaton.

EXPANSION OF LIQUIDS.

At 32° Fahr.	At 212° F.	Expansions.	Authorities.
1,000,000 parts of mercury become	1,018,153	1 in 55	Regnault.
" " water "	1,046,600	1 in 21·3	Dalton.
" " oil "	1,080,000	1 in 12·5	
" " alcohol "	1,111,000	1 in 9	

It will be seen from this last table, that liquids expand much more rapidly than solids, and differ in that property to a much greater extent, the most volatile being the most expansible.

The amount of force exerted by the expanding or contracting of a body under varying changes of temperature is equal to that which would be required to elongate or compress it to the same extent by mechanical means. According to Barlow, a bar of malleable iron, 1 square inch in section, is stretched $\frac{1}{10,000}$th of its length by 1 ton weight; a similar elongation is produced by a rise in temperature equal to about 16° Fahr. The difference between the summer and winter temperatures in this climate is sufficient to cause an iron bar, fastened by its extremities to exert a strain of many tons on the square inch. In engineering and other works it is necessary to make some provision for expansion and contraction. Instances of it are familiar in the cracking of glass and cast iron: the sudden application of heat produces a sudden dilatation on the surface, which is torn away as it were from the interior and colder portions. The unequal contraction due to sudden cooling may produce a similar effect. In the application of solders and cements, regard must be had to the relative expansions of the solders and the bodies soldered. Iron, platinum, and glass do not greatly differ in their rates of expansibility, and hence those two metals may be soldered into glass, whereas silver, gold, copper, and some other metals differ greatly in their rates of expansion from glass, so that when soldered into it, they separate as the joint cools.

Reference has been already made to the three methods concerned in the equilibrium of temperature. But we may be allowed in this place to state a few of the results of modern scientific enquiry on those important processes.

And first, as to conduction. Several distinct sets of investigations have been made as to the relative conducting power of different solids. Wiedemann and Franz ('Pogg. Annal.' lxxxix.) employed equal bars of the substances, and exposed one extremity of each to a uniform source of heat: the progress of the temperature along each bar was measured at intervals of 2 inches by means of a thermo-electric arrangement. Their conclusion was, that the conducting power of metals for heat proceeds in the same order as their electrical conducting power. Calvert and Johnson ('Phil. Trans.,' 1858) employed two vessels of vulcanised India rubber on account of its low conducting power, and passed in succession bars of metal (each 2·36 inches long, and 0·393 inch square), through an opening in one of the sides of each vessel, into which it projected one-sixth of its length, the portion outside and between the two vessels being covered with vulcanised India rubber. A given weight of cold water, sufficient to cover the bar, was poured into one of the vessels and the temperature carefully noted, while into the other vessel was poured a given weight of water at 194°, that temperature being maintained for 15 minutes by the occasional injection of steam. The temperature of the colder vessel was then taken, and a comparison of its rise in temperature when bars of different metals were employed, gave the relative conducting power, correction being made for the loss of heat by radiation and transfer from one vessel to the other. The following table, based on these experiments, represents rather the order of conductability than the conducting power of the metals, for in order to obtain this, it would be necessary to repeat the experiments with bars of the same metals of different lengths:—

Metals Employed.	Rise in Temp. Centigrade Scale.	Mean Conductability. Silver = 1000.
Silver	31·90	1000
Gold	31·30	981
Gold alloy $\frac{991}{1000}$ . . .	26·80	840
Rolled copper	26·95	845
Cast copper	25·87	811
Mercury	21·60	677
Aluminum	21·20	665
Rolled zinc	20·45	641
Cadmium	18·40	577
Bar iron	13·92	436
Tin	13·45	422
Steel	12·65	397
Platinum	12·15	380
Sodium	11·65	365
Cast iron	11·45	359
Lead	9·17	287
Antimony	6·85	215
Bismuth	1·95	61

Of the metals employed in obtaining the above results the platinum, aluminum, iron and sodium were commercial samples: the other metals are supposed to have been chemically pure, and this is a point of great importance since the presence of small quantities of alloy greatly impairs the conducting power. The presence of carbon in iron, exerts a similar effect. Taking silver at 1000, and bar iron at 436, steel was found to be 397, and cast iron 359. Mercury in the above table is stated too high; the result being probably influenced by convective currents which were not counteracted.

It has been shown by De Senarmont ('Ann. de Chimie,' 3, Serie xxi. xxii.) that the conducting power of homogeneous solids, and of crystals which belong to the regular system, is uniform in every direction, yet in crystals which do not belong to a regular system the conducting power varies in different directions with respect to the optic axis. For example, if a slice of quartz be cut parallel to the axis of the prism, and another slice cut at right angles to that axis, and a silver wire be passed through the centre of each plate so that the other ends may be heated in a flame, a film of bees' wax smeared over each section will be melted differently when the wire is heated. In the plate cut across the axis, the wax will be melted in the form of a circle with the wire in the centre; while on the other plate the wax will be melted in the form of an ellipse, the long axis of which coincides with the optic axis of the crystal, thereby showing the superior conducting power in this direction than in the one at right angles to it. De la Rive and De Candolle long since showed that wood conducts heat much better with the grain than across it, and Tyndall ('Phil. Trans.' 1853) has proved that heat passes rather more rapidly in a direction from the external surface towards the centre than in a direction parallel with the ligneous rings, the greatest conducting power coinciding with the direction of greatest porosity and readiest cleavage.

Heat is reflected from different substances very unequally. The reflective power is greatest in polished metals, but they differ greatly among themselves. Out of 100 rays, according to Melloni, silver reflects 90, bright lead 60, and glass only 10: the remainder are absorbed. It has been estimated that the sun's rays, in traversing a column of air=6000 feet high, lose one-fifth of their heat by absorption. But Melloni was the first to make known the remarkable fact that the amount of heat absorbed by the same body varies with the source of the heat, with the exception of lamp black, which appears to absorb all the rays which fall upon it from whatever source. Melloni used as sources of heat the naked flame of an oil lamp, a platinum wire heated to redness in the flame of a spirit lamp, a sheet of copper heated to between 700° and 800° in a current of hot air rising from a lamp beneath it; and a copper canister filled with boiling water. The ball of the thermoscope covered with lamp black, may evidently be placed at such a distance from each of these sources of heat that the liquid shall stand in each case at the same point, so as to indicate the same temperature. Noting these distances and covering the ball of the thermoscope with another substance instead of lamp black, the instrument will apparently receive different proportions of heat, although placed at the distances at which when coated with lamp black the heat appeared to be equal. For example, if the absorption of lamp black from each source of heat be=100, the thermoscope coated with white lead at the same distance from the naked flame as before indicated only 53. The following table will show the variations in this respect, or the relative absorbabilities of different kinds of heat.

Absorbing Surface.	Naked Flame.	Incandescent Platinum.	Copper at 750° F.	Copper at 212° F.
Lamp black	100	100	100	100
White lead	53	56	89	100
Isinglass	52	54	84	91
Indian ink	96	95	87	85
Shell lac	43	47	70	72
Polished metal	14	13·5	13	13

Melloni also discovered remarkable differences in the power of certain bodies to transmit heat through them. Those which were transparent to heat he termed *diathermanous* or *diathermic* (from δια through and θερμος hot) while those which do not allow heat to pass are termed *athermanous* or *adiathermic*. Bodies that are transparent to light are by no means equally so to radiant heat. There is only one known solid that approaches to perfect diathermacy, and that is rock salt. Colourless gases are diathermanous in the highest degree; but all liquids hitherto examined have considerable absorptive action on the thermic rays. A fuller notice of this subject will, however, be given under RADIATION. For other important divisions of our subject we refer to LATENT HEAT; SPECIFIC HEAT; STEAM; DEW; EVAPORATION; BOILING OF LIQUIDS; EBULLITION; FREEZING; CRYOPHORUS; and some other kindred subjects.

Respecting the chemical agency of heat we give no details, seeing that no chemical operation can be performed without some disturbance of temperature or some alteration in the latent and specific heats of bodies. We cannot dissolve any salt in water without a disturbance of temperature, or combine or decompose substances, without similar and often very energetic manifestations of heat.

We must however just refer to what is called the mechanical theory of heat, which has of late years excited revived attention in consequence of the experiments of Joule ('Phil. Trans,' 1850) on the definite amount of heat developed by friction. The mathematical theory of heat started by Carnot was favourable to Joule's result, and has been revived by Clausius, Rankine, W. Thomson, and others. The reader interested in the subject will find an excellent resumé of the theory of the mechanical action of heat or thermo-dynamics by Professor Rankine in Nichol's 'Cyclopædia of the Physical Sciences.' The principle sought to be established by this theory is as follows:—that in all cases where mechanical effect is produced by heat, a quantity of heat is used up proportional to the mechanical effect produced; and conversely that the same quantity of heat can be again generated by the expenditure of just so much mechanical effect. Thus it appears from Joule's experiments that the actual quantity of heat developed by friction, depends simply on the amount of force expended, and not on the nature of the substances rubbed together. When water, for example, is agitated by means of a horizontal brass paddle-wheel, made to revolve by the descent of a known weight, the temperature of one pound of water is raised one degree Fahr., by the expenditure of an amount of force, sufficient to raise 772 lbs. to the height of one foot. So also when cast iron is rubbed against iron, the force required to raise 1 lb. of water 1° Fahr. is about 775 lbs., and by the agitation of mercury with an iron paddle wheel 774 lbs. These results are the means of a large number of experiments, and the conclusion drawn from them is, that the quantity of heat, capable of raising the temperature of 1 lb. of water (between 55° and 60°) by 1° Fahr., requires for its evolution the expenditure of a mechanical force, equal to the raising of 772 lbs. one foot. This is the mechanical equivalent of a unit of heat, and is known as Joule's equivalent. Expressed in terms of the French metrical system the heat capable of raising one gramme of water 1° C. is equivalent to a force which would lift 423·55 grammes through a height of 1 metre. But not only heat and motive power, but all other kinds of physical energy, such as chemical action, electricity, and magnetism, can be experimentally proved to be convertible and equivalent; that is, any one of these kinds of force may by its expenditure be made the means of developing any other in certain definite proportions.

There are certain reservations to be made in using such words as *heat* and *temperature*, but our remarks on this subject had better be deferred until we come to speak of the method of graduating thermometers. See THERMOMETER.

HEBREW LANGUAGE forms a branch of that extensive family of languages known by the name of Semitic; a name which is derived from the real or supposed descent of the people who speak these languages from Shem the son of Noah. The Semitic languages may be divided into three branches: the Arabic, to which the Ethiopic is closely allied; the Aramæan, consisting of two dialects—the Babylonian or East Aramæan (sometimes but erroneously called Chaldee), and the Syriac or West Aramæan; and the Hebrew, to which the Phœnician and Punic are closely related. Of these languages the Arabic is the most copious, and the Aramæan the poorest and least developed; the Hebrew holds an intermediate rank between these, being more perfect than the Aramæan, and inferior to the Arabic.

The Hebrew language derived its name from the Hebrews, who date their origin from Abraham, who is called 'the Hebrew' (הָעִבְרִי) in Gen. xiv. 13. The etymology of this word is doubtful. According to the Jews it is derived from Eber (עֵבֶר), an ancestor of Abraham (Gen. x. 24, 25; xi. 15); but Gesenius and many other critics maintain that Eber cannot be regarded as a historical person, and that his name has been invented in the same manner as the names of Ion, Dorus, Æolus, &c, by the Greeks, to account for the origin of the people. It has been supposed with some probability that the name of 'Hebrew' was originally applied to designate all the Semitic nations west of the Euphrates, which appear to have emigrated from Mesopotamia. According to this etymology, the word 'Hebrew' is derived from the root עָבַר, 'to pass over.' This appears to have been the opinion of the translators of the Septuagint, who render Gen. xiv. 13, 'Abram the Hebrew,' by Ἄβραμ τῷ περάτῃ, that is, 'Abram the passer-over.' All the descendants of Abraham were, according to this view, originally called Hebrews; and the name was only restricted afterwards to the inhabitants of Palestine. (See Ewald, 'Hebrew Grammar,' § 3; and Gesenius, 'Hebrew Lexicon,' under עִבְרִי.) This name is never applied to the language of the Hebrews in the Old Testament; in Isaiah xix. 18, it is called the language of Canaan (שְׂפַת כְּנַעַן); and in Isaiah xxxvi. 11, 2 Kings xviii. 26, 2 Chron. xxxii. 18, and Neh. xiii. 24, the Judaic or Jewish language (יְהוּדִית). The language spoken in Palestine in the time of Christ is frequently called Hebrew (Ἑβραϊστί) in the New Testament (John v. 2; xix. 13; Acts xxi. 40; xxii. 2; xxvi. 14); by which the Aramæan is probably intended. In the writings of the Rabbinical Jews the Hebrew is generally called the 'holy language' (לְשָׁן הַקֹּדְשָׁא).

The Hebrew language appears to have been formed in Palestine by a union of the ancient Aramæan, which was brought by the Abrahamites from Mesopotamia, with the Phœnician or Canaanitish, the language of the original inhabitants of the country. That the Phœnician and Hebrew languages were very closely allied is evident from the Phœnician names of persons and places, and from the specimens of the Phœnician language which we possess in coins and inscriptions. (Bochart, 'Geographia Sacra,' b. ii. cc. 1–7; Bellermann, 'Handbuch der Bibl. Lit.,' vol. i. sect. 56; Bellermann, 'Versuch einer erklärung

der punischen Stellen im Pönulus des Plautus;' Dessen, 'De Phœnicum et Pœnorum inscriptionibus,' Berl. 1810; Dessen, 'Bemerk. über phönizische und punische Münzen;' Gesenius in an Excursus entitled 'Über die phöniz. und punische Sprache und ihr Verhältniss zur hebräischen,' in his 'Geschichte der Hebr. Sprache;' Gesenius, 'Versuch über die malthesische Sprache,' 8vo, Leip. 1810; 'Paläographische Studien, über phöniz. und punische Schrift,' 4to, Leip. 1835; E. Rénan, 'Histoire Générale des Langues Semitiques,' Paris, 1855; M. A. Levy, 'Phönizische Studien,' chiefly relating to Phœnician inscriptions on gems, seals, &c., Breslau, 1858.) The long settlement of the Hebrews in Egypt, and their forty years' wandering in the wilderness, must have had an important influence upon their language; but the number of Egyptian words received into it appears to have been small.

Many critics have divided the history of the language into four periods:—I. From Abraham to Moses. II. From Moses to Solomon. III. From Solomon to the Babylonish captivity. IV. From the Babylonish captivity to its final extinction as a spoken language. But there are in reality only two periods in which any difference can be traced in the language; the first extending from the time of Moses to the reign of Hezekiah, and the second from the reign of Hezekiah to its final extinction as a spoken language. The language in which the Pentateuch is written differs so little from that of David, Solomon, and Isaiah, who lived many centuries after the time of Moses, that many critics, supposing it impossible that a language should have remained stationary for so many centuries, have maintained that none of the books of the Old Testament were written previous to the time of David and Solomon. It is not very easy to disprove this opinion; but the remarks of Ewald on this subject appear worthy of attention. He observes in his 'Hebrew Grammar,' § 7 (Eng. trans.), that "the Hebrew language in the first four books of the Pentateuch, which contain records of unquestionable antiquity, partly by Moses or from his time, appears already, a few minutiæ excepted, fully developed.

"From Moses until about the year 700 it underwent two changes; for as the structure of the Semitic language is in general more simple, so also is it less changeable than that of languages of greater development, as Sanskrit; to which is to be added, that in that period the Hebrews did not experience those influences which materially affect a language; they did not advance much in civilisation, were never long subjected to nations of foreign tongue, and lived almost entirely separated from all nations, especially from nations of foreign language. Their language, therefore, advanced little in development, but it also suffered little from corruption. There are, however, in those books of the Pentateuch some certainly important differences which afterwards disappear, and many differences of that kind have become less distinguishable by us, because the more modern punctuation has treated all words according to one standard, and that the standard of the language at a late period." The study of the Hebrew language appears to have been greatly promoted by the schools of the prophets, which were founded by Samuel; and it is to the influence of these schools that we are probably indebted for the lyric poems of David and the didactic and amatory poetry of Solomon.

The conquests of the Assyrians and Chaldæans from about B.C. 720 tended to introduce the Aramæan language into Palestine. It appears from Isaiah (xxxvi. 12) that the principal people in Judæa, even in the reign of Hezekiah, found it necessary to study Aramæan. The Aramæan colonies (2 Kings, xvii. 24), which were planted in the kingdom of Israel to supply the place of the Israelites who had been carried into Assyria by Shalmaneser, must have caused the spread of the Aramæan language in the northern parts of Palestine even before the destruction of the kingdom of Judah. The long residence of the Jews in Babylon after the destruction of Jerusalem by Nebuchadnezzar, caused the extinction of the Hebrew as a spoken language, at least among the common people. After their return to Judæa, according to the edict of Cyrus, it appears from a passage in Nehemiah (viii. 8), that the common people did not understand the Scriptures when read to them in the Hebrew language. But Hebrew continued to be spoken by the upper classes for a considerable time after the Babylonish captivity. The prophecies of Haggai, Zechariah, and Malachi, who lived in the latter part of the 6th century, are written in tolerably pure Hebrew. The inscriptions of the coins of the Maccabees are in Hebrew; and the Hebrew language does not appear to have been discontinued in writing and conversation among the upper classes till the century preceding the birth of Christ.

But the Hebrew, from the period of its extinction as a spoken language, has been always more or less cultivated by the Jews. After the destruction of Jerusalem by the Romans, numerous schools were established by the Jews, in which their language and literature were taught. Of these schools the most celebrated were those of Tiberias and Babylon. The Mishna, which contains the traditions of the Jews and interpretations of the Scriptures, is supposed to have been compiled in the latter part of the 2nd or the beginning of the 3rd century, by Rabbi Jehuda. The Mishna was considered from this period one of the principal works of Hebrew literature, and the rabbis of Tiberias and Babylon wrote numerous commentaries upon it. These commentaries were at length collected into two separate works, and entitled the Jerusalem and Babylonian Talmuds. The Jerusalem Talmud appears to have been compiled in the 3rd or 5th century, by Rabbi Jochonan; and the Babylonian Talmud in the 6th century, by Rabbi Asci. Each Talmud is divided into two parts: the Mishna, or text; and the Gemara, or commentary. The 'Mishna' has been edited by Surenhusius, 6 vols. fol., Amst., 1698. The Babylonian Talmud was published at Berlin and Frankfort, 12 vols. fol., 1715; and the Jerusalem Talmud at Amsterdam, fol., 1710. To the same schools we are also indebted for the system of punctuation and accents which we have in the Hebrew Bible. This system, which no doubt represents faithfully the traditional interpretation of the Scriptures and pronunciation of the language by the Jews, is entitled Masora (מְסוֹרָה), that is, "tradition." It is uncertain how long the school of Tiberias lasted; but the Babylonish school was broken up by the Arabs A.D. 1040, after a long period of prosperity, and most of the scholars took refuge in Spain, where they founded schools in most of the principal cities. These schools produced a succession of writers, of whom the most celebrated was Maimonides [MAIMONIDES, in BIOG. DIV.], who lived at the latter end of the 12th century. After remaining in Spain for nearly four centuries, they were banished by the Christians in 1492.

The Christians paid very little attention to the Hebrew language before the Reformation. The publications of the Buxtorfs in the 17th century tended to diffuse the language among Christians, but their works contained no philosophical views of the language, since they implicitly followed the decisions of the Masorites. The Grammar of Schultens, which appeared in 1731, and which may still be consulted with great advantage by Hebrew scholars, contained a much clearer development of the principles of the language than the Buxtorfs had given. His knowledge of Arabic enabled him to compare the forms of that language with the Hebrew, and thus to draw the attention of scholars to the important fact, that the study of the cognate languages is necessary to obtain an accurate knowledge of Hebrew. But the publications of Gesenius and Ewald, in the present century, have done more to facilitate the acquisition of the language than the works of all preceding writers.

It appears probable that the language of a country, which was divided both physically and politically into several parts, must have contained various dialects; but this cannot easily be proved, since almost all the Hebrew writers belonged to the kingdom of Judah. The language of Galilee and the northern parts of Palestine appears at all times to have inclined to the Aramæan; in the time of Christ, the Galilæan dialect differed from the language spoken in Judæa. (Matt. xxvi. 73.) In the book of Judges (xii. 6), the pronunciation of the Ephraimites is distinguished; and many critics think that they can discover traces of the northern dialect in the song of Deborah. (Judges, v.)

Few literary subjects have occasioned greater discussion than the letters, vowels, points, and accents of the Hebrew language. But with regard to the letters it appears probable, that the present square characters in which Hebrew is written were not employed previous to the Babylonish captivity, but that the Phœnician letters were used, which are still preserved with a slight alteration in the Samaritan alphabet. According to the Jewish tradition, the present square characters, which belong to the East Aramæan language, were first introduced by Ezra when he revised the canon of Scripture; but they could not have been universally adopted till a later period, since the Samaritan Pentateuch, which was not introduced into Samaria till after the Babylonish captivity, was written in the ancient character, and the coins of the Asmonæans in the 2nd century before Christ also employ the same character. It is difficult to say when the change was introduced. It has been conjectured that the square characters were in use in the time of Christ, from his referring to the letter *yod* as the smallest letter in the alphabet; a fact which is true of the present Hebrew alphabet, but would not apply to the ancient Hebrew or Phœnician alphabet.

It is a characteristic of the Hebrew language, according to the system of most modern Hebrew grammars, that the alphabet consists only of consonants, and that the vowels are expressed by means of small points placed above and below the letters. The antiquity of these points has occasioned great controversy among the learned. Some have maintained that the points are as ancient as the letters, and that both the points and letters were taught Moses by God himself; others, that the points were first introduced by Ezra when he transcribed the Scriptures in the present square characters; others, that the Hebrews had originally three vowel points, *a*, *i*, and *o*, answering to the three letters א י, ע, and that the present system of punctuation was not introduced till the time of the Masorites; but it is now generally considered by eminent Hebrew scholars, Gesenius, Winer, Ewald, &c., that the whole system of punctuation was first introduced by the Masorites, of whom some account has been given above, perhaps as early as the 6th or 7th century, and certainly not later than the 10th or 11th. It appears certain from many circumstances that the Hebrew letters were originally written without points. They are not found in ancient Jewish coins and inscriptions; they are not once mentioned or alluded to in the Talmud; they appear to have been unknown to Origen and Jerome; the ancient versions, such as the Chaldee paraphrases of Jonathan and Onkelos, and the Greek translations of Aquila, Symmachus, Theodotion, and the Septuagint, must have been made from Hebrew manuscripts without points, since they frequently give a different interpretation to the words from that which they must mean according to the present system of punctuation; and it is allowed that all the other Semitic languages had anciently no points. The best arguments on both sides of the question are given in Buxtorf's 'Tiberias, sive Commentarius Masorethicus,' 4to, 1620, in which the antiquity of the points is maintained, and in Capellus's 'Arcanum Punctationis revelatum,' 4to, 1624, in which their antiquity is denied. Further information on the subject will be found in most grammars. The system of accentuation depends on that of points, and was in all probability introduced at the same time. The accents mark the relation of one word to another in a sentence, and thus serve an important purpose in the syntax of the language. Many scholars have considered the accents almost useless; but one of the most eminent Hebraists of the present day remarks (Ewald, 'Hebrew Grammar,' § 642, Engl. Transl.), "We everywhere find a beautiful harmony between the accentuation and the syntax, so that they mutually support and explain each other. Whether we set out from the syntax, and learn to comprehend it without knowing any thing of the accentuation, or whether we proceed from the accentuation to the syntax, an accurate investigation will always lead to the same results, so that he who thoroughly understands the syntax is for the most part clearly possessed of the accentuation also, and he who understands the latter becomes throughout more easily at home in the former. This is, however, at the same time the best commendation of the accentuation." We must distinguish, however, the accentuation of the historical and poetical books. The remarks of Ewald apply only to the accentuation of the historical books. Many of the accents in the poetical books serve the same purpose as those in the historical; but the greater part were intended to indicate the tone according to which the Scriptures were chanted in the synagogue. The accents are explained with great clearness in Stuart's 'Hebrew Grammar.'

HEBREWS, EPISTLE TO THE, a book of the New Testament. The absence of the initiatory formula usual in the apostolic epistles has led some to doubt whether this book is an epistle or a dissertation. But it contains allusions to particular circumstances, which prove it to be an epistle (v. 11, 12; vi. 9, 10; x. 32-34; xiii. 19, 22, 23). The general opinion respecting the persons to whom this Epistle was addressed is that they were the Jewish converts in Jerusalem or Palestine generally. This opinion, as Michaelis has shown, is supported by the contents of the book itself. (Marsh's 'Michaelis,' vol. iv. pp. 193-7.) Others suppose it to have been addressed to the Jews of Asia Minor, and Dr. Noesselt contends for its having been written to the Thessalonians. Concerning the language in which this epistle was written critics have been much divided; some supposing that it was written in Greek, and others that it was written in Hebrew and translated into Greek. The latter opinion was held by Clement of Alexandria (who states "that it was written by Paul in the Hebrew language for the use of the Hebrews, and that Luke translated it for the benefit of the Greeks"); by Eusebius, and by other fathers; and is strongly advocated by Michaelis. The other opinion is supported by Lardner, Macknight, Rosenmüller, Professor Stuart, and most modern commentators.

The author of this Epistle is equally uncertain. The general voice of tradition assigns it to the apostle Paul, but it has also been ascribed to Barnabas, to Luke, to Silas, and to Apollos.

In the first ages of the church it appears to have been generally considered as a production of the apostle Paul, though great doubts were very early entertained on the subject. In the Alexandrian church we have the testimony of Pantænus (A.D. 180) to its Pauline origin, as well as that of Clement, in the passage quoted above, and in other parts of his writings. These testimonies are preserved by Eusebius ('Hist. Eccles.,' book vi. c. 14). Eusebius also quotes a passage from Origen (*Ibid.*, c. 25), which has been variously understood, but which seems to imply that an objection had been raised against the Pauline origin of the epistle from the superiority of its style to that of the acknowledged Epistles of Paul, and that to meet this objection Origen supposed the sentiments to be Paul's, but the diction that of some other person, a disciple of Paul. But he adds: "If any church therefore hold this epistle to be Paul's, let it receive commendation for this. For it is not without reason that the ancients have handed it down as Paul's." In Origen's own writings it is frequently quoted as being written by Paul; and after his time the Alexandrian fathers unanimously ascribe it to the same apostle. Turning to the Eastern church we find passages in the writings of the fathers, which are thought by some to be indirect quotations from this epistle. The earliest direct testimony is that of Eusebius, who mentions fourteen epistles as being clearly and certainly Paul's, but adds that "some have rejected that which is written to the Hebrews, alleging, with the church at Rome, that it is spoken against as not being Paul's." He frequently cites it as written by Paul. The Western church seems to have been greatly divided on this subject from about the close of the 2nd to the middle of the 4th century, when Jerome states that the Epistle was received as Paul's by all the Greek and some of the Latin churches, though rejected by most of the Latins, who ascribed it to Barnabas or Clement of Rome, but held it in high esteem, and read it in their churches. Jerome himself, and Augustine, constantly refer to it, sometimes as an apostolic production, and sometimes as St. Paul's. Their authority appears finally to have established the belief in its Pauline origin among the Western churches. The modern advocates of the same opinion have attributed the doubts which prevailed in the Western church at the end of the 2nd century to the disputes with the Montanists, who relied on this Epistle in support of some of their opinions. On the other hand, those who believe that Paul did not write the Epistle ascribe the strong testimony of the Alexandrian fathers in its favour to their great fondness for the allegorical interpretation of Scripture, which the style of this Epistle is thought to sanction. The passage in 2 Peter iii. 15, is thought by some to refer to the Epistle to the Hebrews.

The internal evidence in favour of Paul being the author is drawn from the reference (c. xiii. v. 23) to Timothy, who is known to have been Paul's intimate friend and frequent companion; and from other incidental allusions (see x. 34; xiii. 18, 19, 24). In the arrangement of the Epistle, the former part being doctrinal and the latter part hortatory; in the mode of using quotations from the Old Testament and the style of argument adopted; in the doctrines most prominently stated and the phraseology employed; there are great resemblances between this book and St. Paul's acknowledged epistles. (For examples see Prof. Moses Stuart's 'Commentary on the Hebrews,' Introd., sects. 20–24, and Horne's 'Introduction,' vol. iv., p. 415, &c., ed. 1834.) The chief objections against the Pauline origin of the epistle are drawn from the absence of the usual address at the beginning, the superiority of the style to that of Paul's acknowledged epistles, and the resemblance between its style and that of the Alexandrian school. The points above stated are discussed with great ability and candour by Prof. Moses Stuart in favour of the Pauline origin of the epistle, and Prof. Bleek ('Der Brief an die Hebräer') on the other side. On the whole, the arguments of St. Paul being the writer seem to be irresistible.

The opinions which assign the authorship to Barnabas, Apollos, Luke, and Silas, rest on very slight grounds. The second of them was first started by Luther, a conjecture founded on the resemblance which the epistle bears to what we might expect to have been written on such a subject by a man of the character given to Apollos in Acts xviii. 24–28.

The date depends partly on the settlement of the former question. The internal evidence of the Epistle shows that it was written while the temple at Jerusalem was standing (see viii. 4–5; ix. 9), and probably not long before its destruction in A.D. 70. If Paul was the author, it was probably written during his first imprisonment at Rome, and immediately before he was released (see xiii. 18, 19, 23). Accordingly most critics refer it to A.D. 61 or 62; some say A.D. 58.

The canonical authority of this Epistle depends partly on its authorship; but may be argued on other grounds. It is repeatedly quoted by Clement of Alexandria, and apparently by Barnabas, Hermas, Polycarp, Ignatius, and Justin Martyr. It is contained in the Peshito Syriac version, the date of which is not later than the 2nd century, and in the old Latin versions made about the same period. From that time the questions of the canonical authority and the authorship are very much mixed up together.

The design of the writer of this Epistle appears to have been to sustain the faith of those to whom he wrote, while they were suffering under persecution and inclined to apostacy. After urging them to the practice of various Christian duties, he concludes with the usual salutations. In warmth of feeling, elegance of language, and force of argument, this epistle yields to no book of the New Testament.

The separate commentaries on this book are extremely numerous. Among the more recent are Barnes's 'Notes, Practical and Explanatory,' 1843; Tholuck's 'Commentar sum Briefe an die Hebräer,' 1840; the 'Commentar zum Briefe an die Hebräer,' 1858, of Delitzsch. In Kitto's 'Cyclopædia of Biblical Literature,' a list of commentators is given.

HECATE, one of the ancient Greek divinities, the daughter of the Titan Perses and Asteria, according to Hesiod ('Theog.,' 411), but others give to her a different parentage. She appears to have been originally a Thracian deity, and regarded as a Titan of unusual powers. She was a mystic goddess, and identified, more or less, with several ancient Greek deities, but her attributes correspond in most respects with those of Artemis; and it has therefore been conjectured that she may originally have been the same as Artemis. Her name, the feminine of Hecatus ("the far-shooting"), one of the names of Apollo, the brother of Artemis, is thought to favour this supposition. Hecate presided over hunting and fishing, the deliberations of the popular assembly and the courts of justice. She seems also to have appropriated to herself part of the duties of Persephine (Proserpine); since she was regarded as the mistress of the lower world, the arbiter of the souls of the departed, and the patroness of magic. She was considered a beneficent deity, who answered the prayers of her worshippers. Her statues were placed at cross-roads and before houses. She was held in much respect in Athens, where she was regarded as the patroness of families and children. She was greatly venerated by the inhabitants of Ægina, who held a festival once a year in honour of her; which was said to have been instituted by Orpheus. (Pausan., ii. 30.) Representations of her are very numerous. Sometimes she appears as a three-headed being, attended by the Stygian dogs; sometimes with three bodies, when she is the same as the Diana Triformis of the Romans (Virgil, 'Æn.' iv. 511). We give an engraving of Hecate (or Diana Triformis), from a votive statue, 2 feet 6 inches high, in the

British Museum. Statues of this kind were placed in towns and villages where three roads met. The figures held various symbols, as a globe, a patera, twisted cords, serpents, a torch, &c. The hands with the attributes in the Museum statue, are however modern.

Statue of Hecate from the British Museum.

HEDERIC ACID. An acid, of uncertain composition, extracted from ivy-berries. It crystallises in needles or thin plates, which are colourless and inodorous, but possess the intensely bitter taste of the ivy. It is insoluble in water and ether, but soluble in alcohol. In contact with concentrated sulphuric acid it strikes a fine purple colour.

HEDERINE. An alkaloid found in ivy-berries. It requires investigation.

HEDGE, one of the most lasting and effectual of our fences. When hedges have been well made, and are kept in good order, nothing can surpass them, except well-built stone or brick walls, and even these are far less effectual in keeping out trespassers of every description.

Hedges are made of various kinds of shrubs and trees, trained so as to throw out numerous branches along the stem from the surface of the earth upwards; this is done by judicious pruning when they are young. The head being cut off and the side branches shortened, numerous smaller branches spring out, which are shortened in their turn, and form a very compact mass, consisting of the ends of stumps and branches pointing in every direction. Those shrubs which are of a thorny nature are best adapted for hedges. Holly, which bears prickles on the edges of the leaves, is on this account by far the best shrub to form a hedge. But it has a great inconvenience in its very slow growth, and except in very old gardens, which have been surrounded by a holly-hedge before the present generation was born, it is very seldom that such a hedge is met with. The high price which the nurserymen charge for this plant is another reason why it is seldom planted.

In forming a holly-hedge the ground should be prepared by trenching and abundant manuring: the plants should be most carefully planted after midsummer, or immediately before the usual rains which come at that season. There should also be a portion of virgin soil for the roots to spread in; and in planting they should be well divided, to give them the greatest extent from which to draw their nourishment. The earth should be well pressed to them by treading it down; and in case of a continued want of rain, they may be occasionally watered, late in the evening, or early in the morning. By a little attention to them in the first year, they will form a good fence several years sooner than those which are comparatively neglected. The plants which are usually put in are three years old; but if they could be transplanted at once from the seed-bed, they would sooner come to perfection; and by being cut down and pruned earlier, would lay the foundation of a closer and better hedge. Next to holly, as forming a close and durable hedge, is the yew: it bears very close clipping, and forms a thick hedge and good shelter all through the year. For gardens and nursery-grounds, where shelter and occasional shading are required, the yew-hedge is preferred; but in all places where cattle are put to pasture, the yew should never be permitted to grow. Many valuable horses and cattle have been destroyed by grazing in places where yew-trees grew; and notwithstanding the instinct which leads animals to reject food which is hurtful, they greedily eat the yew leaves in spring. The same may be said of box.

The various kinds of thorns are peculiarly adapted to form hedges, and they are consequently by far the most common plants of which a live hedge is formed.

For high hedges and strong fences the hornbeam and a variety of the beech which throws many branches from the stem are extensively used in old gardens, where geometrical figures and numerous angles are admired.

Where it is desirable that the hedge should arrive very rapidly to such a size as to be a good defence against cattle, elder may be planted. Elder grows very rapidly, and throws out many long hollow branches, which soon become hard, and are admirably calculated for a fence, and cattle will not eat the leaves; but it is never very close or ornamental; and as it requires to be cut down frequently, it displays very unsightly knots and stumps when it has acquired a certain age.

Sweetbriar is ornamental, and forms a good fence against sheep. It is chiefly confined to flower-gardens and enclosures in pleasure-grounds.

Many other shrubs might be named, such as the *Pyrus japonica*, which is prickly, grows close, and bears a beautiful flower. It is as hardy as any native British plant, and will bear cutting and training as well as any of them. Hitherto no hedges have been made of this shrub, except a few in the gardens of nurserymen; but there is no doubt that if many young plants were wanted for hedges, they would soon be produced at a reasonable price. The privet is a very common and quick-growing shrub, which is frequently planted as a hedge where cattle are not admitted; but of all shrubs, the most common and most useful for the purpose of hedges are the black and white thorn, and they almost universally form the quick hedges by which our fields are separated and enclosed.

In order to have a good hedge, the shrubs should be planted in a soil which is naturally strong, but well pulverised, and in which no shrub or tree has lately grown. The best soil is that which is produced by the decomposition of sods taken from commons or old pastures; and it is observed that in new enclosures, where the quick has been inserted between two sods, it always grows luxuriantly, and only requires to be protected, when young, against the cropping of cattle and sheep, which are fond of the young tender shoots. The usual mode is to insert, in the early part of the spring, a row of quick in the side of the bank, on a level with the surface of the ground, where a sod has been turned over, and forms the base of the bank raised by the earth taken out of the ditch. This quick requires to be protected from cattle or sheep by some fence. [FENCE.] Sometimes the quick is planted in two or three parallel rows on the top of the bank, which in this case is made much wider, with a ditch on each side. A double fence in such case is necessary for its complete protection. When the quick is planted on the top of the bank, the surface sods are reserved to lay at the top; and after being broken and chopped to pieces, are dug into the bank. Stable-dung is frequently dug in at the same time, and is well bestowed: the quicks are then inserted, and well watered. They never fail to come up luxuriantly; and when properly pruned they form a close and impenetrable hedge.

Many think that it is advantageous to prune and cut down the young shoots every year, in order to excite them to throw out fresh ones in greater number. But this is an error, by which the growth of the hedge is much retarded. The shoot should be allowed to grow to its full extent the first and second year; the root will then have struck deep into the ground; and in the third or fourth year the quicks may be cut down to a few inches. They will then send out several fresh strong shoots, which may be cut and pruned to the height and width of the intended hedge.

In Holland and Flanders the hedges are often trained along stakes and rods placed for the purpose, and tied together with osiers. In this case every slender branch is tied to the rods, and they are laid so as to cross each other frequently, and the redundant shoots which cannot be conveniently tied in are cut off. These hedges, when in leaf, look very close and light, and take up very little room; and birds can scarcely harbour in them. It appears at first sight that much labour is required to train hedges in this way; but this is by no means the case. When they have once grown to the proper height they only require to be regularly clipped.

In forming a hedge it is necessary to take into consideration the quality of the soil, the aspect of the bank, and whether the land is porous, or very retentive of moisture. In the first case it will be advantageous to plant the quick in the side of the bank, raising the earth above it to keep in the moisture. A ledge may be made by setting the first sod at a couple of inches from the edge of the ditch.

The water which may fall on the bank and run down the smooth side is arrested by the lodge and soaks into the roots. In the other case the top of the bank is the proper place, and a small concavity may be given to it to retain the water and keep the roots moist.

In a dry soil which does not require draining, ditches are unnecessary, and it is much better to plant a hedge on a little bank formed by a few sods about eighteen inches wide, with a small water-furrow on each side. The whole width need not be above two feet six inches, whereas a bank and ditch take up at least six feet, and the plough cannot go nearer than a foot from the edge of the ditch or the bank. Thus eight feet are taken up by the fence.

When a hedge has been left uncut for several years, it grows wide and high. It requires to be cut down once in seven or eight years; in this case much care is required in the cutting that the shoots may grow out again regularly. The common labourers often do this very carelessly, by cutting the stems downwards with one or more cuts of their bill-hook. The consequence is that the stem is split and shivered, and the rain lodging in the ragged cut injures the wood and causes it to die down farther than it otherwise would. Hence the general maxim of "cutting up," so strongly recommended by all those who give directions about cutting hedges. Portions of the stems are often left of a greater length than the rest for the purpose of holding the bushes, which are generally laid over the cut stumps to protect them against cattle. But it is better to cut the hedge regularly, one row close to the ground, and one a few inches longer; this will strengthen the foot of the hedge, and prevent its being thin and hollow at bottom.

When a hedge has become old, and many of the plants are decayed, it is very difficult to renew it. If young quicks are planted on the same spot, they will scarcely ever succeed, unless very great precautions are taken. The soil is exhausted or deteriorated, and must be renewed: but manuring is not sufficient; fresh earth is required for the new quick. The simplest process is to level the old bank, spread the earth of which it was formed, which will be of great use to the ground where it is spread, and form a new bank in the same place from earth taken elsewhere; or, where it can be done without inconvenience, it is better to make an entirely new ditch and bank, and to fill up the old. This is perhaps the surest as well as the soonest way of having a new hedge which will be permanent.

What has been said of renewing a hedge is equally applicable to repairing gaps in an old one. It is of no use to put in young plants in the old bank. The earth must be removed, and fresh earth put in its place. The old hedge must be cut and trimmed, so that the young quick may not be shaded, and in that case the gap will shortly be filled up, and the hedge be restored as a continuous fence. Where the gaps are very small, and the hedge is not cut down altogether, it may sometimes be advisable to plant hollies or other plants, which will grow well and fill up the deficiency.

Well managed hedges are the most effective fences, the cheapest, and the most pleasing to the eye. It is to the hedge-rows that England owes much of its garden-like appearance; but the trees, which are their chief ornament, are very destructive of the hedge as a fence; and where trees are planted it would be much better if they stood within the bank, without interfering with the hedge. Whether trees can be allowed in hedge-rows, in a perfect system of agriculture, is a question which we will not attempt to answer.

There is a method of repairing hedges which is called "plashing" (*pleaching*). It consists in cutting half through some of the stems near the ground, and then bending the upper parts down in a horizontal or oblique position, keeping them so by means of hooked sticks driven into the bank. Thus a live hedge is made, which fills up the gaps in the same manner as a dead hedge would have done, and the bent stems soon throw out shoots. If the stems are young, and not above the thickness of a finger, an excellent hedge may be thus formed, which, when clipped, will be close and perfectly impervious. But the work is generally done in a very injudicious manner. When a hedge is plashed which has been long neglected, the thick stems, which are hacked through, leaving only a small portion of the under bark uncut, have an unsightly appearance, and seldom throw out shoots near the bottom, where they are most wanted. To plash a young hedge by merely bending the twigs is an excellent practice: but when the stems are thick and old, the only remedy is to cut them down, or make an entirely new bank well planted with quick.

HEIGHTS, MEASUREMENT OF. There are three very distinct ways by which heights may be measured. The first is by observation of the angles of elevation of objects, supposing their distances to be known, which is explained roughly in works on trigonometry and mensuration, and with more precision in those on geodesy. [MENSURATION.] The second serves for the measurement of heights in cases where not only the height of a summit is required, but also that of the slope which leads to it, at different distances from the summit; and this is done by means of the level. [LEVELLING.] The third, which we propose here to describe more particularly, is accomplished by means of the barometer. [BAROMETER.] We may also refer to a fourth method, depending on the diminished temperature at which liquids boil under diminished pressures: for the experimental details of this method, see BOILING OF LIQUIDS.

If we ascend with a barometer through any height, the weight of the column of air which presses on the instrument is diminished, and the counterpoise, namely, the column of mercury under the vacuum, must diminish likewise; that is, the mercury must fall. The amount of this fall depends upon the height in question: and when the relation between the two is perfectly well ascertained, may be made the means of determining it. If the temperature at the higher and lower station were the same in all places and at all times, and if the force of gravity were precisely the same at all heights, one formula would serve for all times and for different places, if the height of the barometer remained always the same at the same height above the sea. In such a case, one observation made in London a hundred years ago, combined with one made at Quito in the present time, would serve to determine the difference of level between those two places. And even as it is, the mean height of the barometer at the two places, when known, could be made to determine the point. But when only one or two observations can be made at each place, the differences of temperature, &c., must be noted and allowed for: and this necessity renders the numerical operations connected with the solution of the problem more intricate than they would otherwise be.

If the temperature were unaltered during the ascent, and the force of gravity also remained uniform, the *logarithms* of the atmospheric pressures corresponding to different altitudes would *decrease* in arithmetical proportion as the altitudes themselves *increase* in arithmetical proportion; that is, the density of the atmosphere *decreases* in a *geometric* progression, as the heights *increase* in an *arithmetic* progression. Thus if at altitudes 0 and h the logarithms of the pressures were k and $k-l$, at an altitude $2h$ the logarithm of the pressure would be $k-2l$, and so on. And since the height of the barometer is proportional to the pressure for the time being, this would lead to an equation of the form

$$z = c\,(\log. h - \log. h');$$

where z is the difference of altitudes at two stations, and h and h' the heights of the mercury at the lower and upper stations.

The constant c might be determined either from theory or actual measurement; for if h and h' were known in any one case, and also z by trigonometrical or other measurement, c might be determined, and being independent of z, h, and h', would then be known in all cases. But in truth c is not to be thus determined, for though independent of h and h', it varies with temperature, the force of gravity, &c.

1. If the temperature either of the higher or lower stations be not the same in different observations, the multiplier c will be of one value or another, depending on the temperatures.

2. If the mercury be not of the same temperature at all times, its specific gravity will vary, so that a given column of it will not represent the same atmospheric pressure at all times.

3. If the force of gravity be taken into account, the pressure taken off by the ascent will be a larger proportion of the whole pressure than was supposed in the investigation of the preceding formula, since it is taken from the part of the atmosphere where the force of gravity is greatest. This is independent of its greater weight as being taken from the densest part of the atmosphere. The latter circumstance has been already taken into account in the formula, and from it comes the law that the logarithms of the pressures diminish in arithmetical progression, since the pressures themselves would diminish in arithmetical progression if the density of the air were the same at all heights.

4. Bessel has recently shown that another correction must be applied, owing to the modifications produced by the existence of a humid atmosphere of peculiar habitudes, *within* the dry or permanently elastic one. After applying all these corrections, the formulæ are determined by the aid of subsidiary or *hypsometric* tables, the best of which are those by Deleros, published in the 'Annuaire Meteorologique,' for 1849. Those containing *also* Bessel's correction are given in the same work by Plantamour, for 1852.

We now proceed to describe two formulæ made on slight differences of hypothesis as to the element of the problem about which we know least, namely, the law of variation of the temperature of the atmosphere. The first formula, which is nearly in the form given by Laplace, is taken from Poisson's Mechanics, and supposes that the air intermediate between the higher and lower stations may be treated as if it had throughout the mean between the temperature of the two stations. The second, taken from Lindenau's Barometric Tables, is on the supposition (which was also made by Euler and Oriani) that the temperature of the air diminishes in harmonic progression through a series of heights increasing in arithmetical progression.

Let h and h' be the heights of the barometer at the lower and upper stations; t and t' the temperatures of the air; T and T' those of the mercury (ascertained by a thermometer whose bulb is in the cistern); r the radius of the earth, and λ the latitude of the place. All the temperatures are in degrees of Fahrenheit. Let

$$=h\left(1+\frac{\mathrm{T}-\mathrm{T}'}{9990}\right)$$

$$c=\frac{60168}{1-\cdot 00257\cos 2\lambda}\left(1+\frac{t+t'-64}{900}\right)$$

$$z=c\,(\log. h-\log. k).$$

Then z itself is a near approximation to the number of yards in the difference of level between the two stations; but if a more exact one be required, it may be found by calculating (using z itself as just found)

$$z = c\left(\log. h - \log. k + 2\log.\left(1 + \frac{z}{r}\right)\right)\left(1 + \frac{z}{r}\right)$$

When the lower station is at a great distance from the higher on the earth's surface, then five-eighths of $\frac{z}{r}$ should be used instead of $\frac{z}{r}$ in the last formula.

The second formula, by M. Lindenau, is as follows, the letters meaning the same things as before; but the degrees are those of Réaumur's thermometer, and the distances are expressed in toises. The toise is 2·1315308 English yards, and a reading of Réaumur is reduced to one of Fahrenheit by the following formula:—

$$\text{Fahr.} = 32^\circ \frac{9}{4}\ \text{Réaum.}$$

$$\text{Let } c = \left(1 + \frac{t+t'}{400} - \frac{(t-t')^2}{160000}\right) \times 9442;$$

$$\text{H} = h\left(1 - \frac{\text{T} - 10}{4329{\cdot}6}\right)$$

$$\text{H}' = h'\left(1 - \frac{\text{T}' - 10}{4329{\cdot}6}\right)$$

Then the number of toises in the difference of elevation of the stations is

$$c\,(\log. \text{H} - \log. \text{H}').$$

The formula which has been generally used is of the form

$$z = a\left(1 + \frac{t+t'}{b}\right)(\log. h - \log. h');$$

and the following are the constants a and b used by the observers whose names are mentioned, all reduced by M. Lindenau to those values which they should have when the thermometer is Réaumur's and the result in toises:—

Ramond	$a = 9437$	$b = 400$
Trembley	$a = 9401$	$b = 361$
Roy	$a = 9388$	$b = 362{\cdot}2$
Schuckburgh	$a = 9400$	$b = 366{\cdot}6$
Deluc	$a = 9220$	$b = 396{\cdot}4$

The preceding are the most exact formulæ for computing the heights required. The late Prof. Leslie has, however, given the following rule, as the simplest approximation for all practical purposes:—"As the sum of the heights of the mercurial columns is to their difference, so is 52,000 to the approximate height in English feet." Lastly, the most complete accounts of this subject will be found in Schumacher's 'Astronomische Nachrichten,' band xv.; by Bessel, and in Biot's 'Astronomie Physique,' tom. iii. Prof. Littrow has given in the first volume of the 'Astronomical Society's Transactions,' a very beautiful method, which dispenses with the use of logarithms.

HEIR, by the law of England, is he who succeeds by right of blood to the real property or lands, tenements, and hereditaments of the deceased owner, designated by the correlative term of ancestor, not given away from him by will. The English law which determines the succession to personal property, when uncontrolled by local custom, is contained in the statutes of distributions (22 & 23 Chas. II., c. 10; 29 Chas. II., c. 3; and 1 Jac. II., c. 17), which are founded upon the provisions of the civil law. The persons so entitled are not called heirs, but next of kin.

The several rules of descent which regulate the right to succeed to real property spring from the system of feudal tenures, but have been somewhat modified by the statute of 3 & 4 Wm. IV., c. 106. [DESCENT; ENTAIL; ESTATE; FEUDAL SYSTEM.]

Heir-at-law, or heir-general, is he who succeeds according to the rules explained in the article DESCENT, where there is no will of his ancestor and no instrument which determines a special course of descent. Heir-special is he who succeeds in the order pointed out by some instrument which determines such special course of descent. [ENTAIL.] Heir-apparent is he whose right of inheritance is indefeasible, provided he outlives his ancestor; as the eldest son. Heir-presumptive is he who, if his ancestor should die immediately, would in the present circumstances be his heir, but whose right of inheritance may be defeated by the birth of some nearer heir; the brother or nephew of a man who has no children is heir-presumptive. Heir by custom is he whose right as heir is determined by certain customary modes of descent, which are attached to the land. [DESCENT; COPYHOLD; GAVELKIND.]

The expression "heirs by devise" has also been sometimes used, though such are not strictly heirs according to the English law; but have been so called inaccurately after the *heres factus* of the Roman law.

The rules of the civil law upon the subject long prevailed in Scotland, both in principle and practice. But various alterations have been made in the Scotch law of inheritance, and now the different descriptions of heirs are far more numerous than in either the English or the Roman law. Heirs-at-law are called heirs whatsomever. Heirs-in-tail, heirs of tailsie, and heirs of provision differ little in their nature. There are also heirs active, heirs by conquest, heirs of line, heirs passive, heirs male, and heirs portioners, the particular distinctions between each of whom it is not necessary here to describe. (See Bell's 'Commentaries and Principles,' and Lord Kames's 'Law Tracts.')

The French law of descent has followed the Roman law, and the obligations and privileges of the heir are essentially the same as there prescribed.

In America the English law of descents has been in most instances rejected, and each state seems to have established rules for itself. There is no entire information upon this subject; indeed chief-justice Reeve in the preface to his 'Treatise on the Law of Descent in America,' has this strong passage, that the nation "may be said to have no general law of descents, which probably has not fallen to the lot of any other civilised country." (Kent's 'Commentaries,' lect. 65.)

The term *heres* in the Roman law has a very different signification from the term *heir* in the English law. The Roman term *hereditas* denoted all the rights and obligations of a testator or intestate; and the *heres*, when his title as such was completed, represented the person of the testator or intestate, and as a consequence succeeded to all his rights and obligations. A man might by his will appoint one *heres* or more, and the property of an intestate might devolve on one *heres* or more; but this made no difference with respect to their character. Each person was *heres* in proportion to his share of the inheritance. The *heres* appointed by will was called *scriptus*, or *factus*, or *testamentarius*; the *heres* who succeeded in case of intestacy, *ex lege*, or *legitimus*, that is, appointed by the law, or *ab intestato*.

An important distinction between *heredes* as established by the old Roman law was this, and the distinction was the same (so far as it could be applicable) both in the case of testacy and intestacy. All persons who were in the power (*potestas*) of the testator, or intestate, during his lifetime, such as children not emancipated, and slaves, were obliged to accept the inheritance with all its burdens; the inheritance, in fact, devolved upon them by the will of the testator, and no act of assent on their part was necessary. Other persons, not in the power of the testator, were only bound to undertake the burden of the testator's debts in case they accepted the inheritance, for which purpose their express assent was necessary. But by the legislation of Justinian, the *heres* in all cases was only answerable for the debts of the testator or intestate to the amount of property which such testator or intestate left behind him, of which, however, the *heres* was required to make an inventory within a certain time. ('Cod.' vi.; 'Tit.' 30, l. 22; 'Instit.' ii. 19.)

The discussion of the various rights and duties of the Roman *heres scriptus* belongs to the subject of wills.

In the case of intestacy, the distribution of the property was analogous to the distribution of an intestate's personal estate by the English law. The Roman law gave no preference to an eldest son over a younger, or to a brother over a sister. Emancipated sons, who, by the strict rule of the civil law, were excluded from the inheritance [EMANCIPATION], were placed by Justinian's legislation on the same footing as children not emancipated. It is unnecessary here to state more minutely the rules which regulated the distribution of an intestate's property. ('Instit.' iii. 1; 'Nov.' 118, c. 1, 2, 4.)

It is important to conceive clearly the fundamental notion of the difference between the Roman *heres* and the English *heir*. The Roman *heres*, when his title to the inheritance was completed, represented the person of the testator or intestate, and so far corresponded to our executor or administrator. His title to the property, as *heres*, was absolute, and derived entirely from him to whose rights and obligations he succeeded. The English *heir*, according to the strict principles of tenure, derives his title to the land not from his immediate ancestor as such, but by virtue of his relationship by blood to the person who acquired the land, deduced through his immediate ancestor. The consequences which flow from these two different notions of the Roman *heres* and English *heir* are numerous and important. They are well stated, in a general way, by Mr. Butler in his note on 'Coke-Litt.,' 191 *a*. The stat. 4 Wm. IV. c. 104, which makes all a deceased person's estate in land liable to the payment of his debts, has materially affected the ancient right of the English heir.

HEIR-LOOMS are such goods and personal chattels as, contrary to the nature of chattels, go to the heir by special custom along with the inheritance, and not to the executor of the last proprietor. [CHATTELS.] They are principally such things as cannot be removed without damage to the inheritance, as chimney-pieces, fixed tables, &c. Deer in an authorised park, fishes in a pond, deeds, charters, and court-rolls, together with the chests in which they are contained, are heir-looms. And so it seems are journals of the House of Lords in the possession of a peer. By special custom in some places, carriages also and household implements may be heir-looms.

The termination "loom" is of Saxon origin, in which language it signifies a limb or member, so that an heir-loom is nothing else but a limb or member of the inheritance. (2 Bl. 'Com.') Chattels are sometimes directed by testators to go to the heir, together with the inheritance, as heir-looms, and though it is the duty of the executors to carry the intention into effect so far as they can, yet the direction does not affect the rights of creditors, neither can it effectually prevent the devolution of the chattels according to their real nature.

HELIACAL (ἥλιος, the sun), a term applied to the rising of a star, when it takes place just before that of the sun. If we suppose a star not very far from the sun's orbit, then as the sun approaches that star it will become for a season permanently invisible, for it will rise after the sun, and set after it also, the heavens remaining too light in the quarter of sunset to permit the star to be seen. But as soon as the orbital motion of the sun has carried it past the star, the latter will begin to rise first, and in process of time will rise so much before the sun as to become visible just before daylight. In this case it is said to rise helically: thus a star sets heliacally before its season of disappearance, and rises heliacally after its reappearance. The successive heliacal risings of stars thus form a continued warning of the seasons, and were used for this purpose among some ancient nations. But since the precession of the equinoxes slowly changes the offices of different stars with respect to the seasons, an ancient record of the time of the year when a given star rose heliacally would enable us to make a rough guess at the number of centuries elapsed since the time of the observation. Upon such a basis Newton rested a great part of his system of chronology, taking the descriptions of the heliacal risings of stars from Hesiod.

HELIACAL CURRENTS. [Electro-Dynamics; Electro-Magnetism.]

HELICIN. [Salicyl.]

HELICOIDIN. [Salicyl.]

HELIOCENTRIC (having the sun as centre), a term applied to the place of a planet, as seen from the centre of the sun, in opposition to its *geocentric* place, as seen from the centre of the earth. [Parallax.]

HELIOMETER (ἥλιος, the "sun," and *μέτρον*, "measure") is the name given by M. Bouguer to a micrometer invented by himself about 1745, by means of which the diameters of the heavenly bodies may be measured with considerable accuracy. In Bouguer's construction the tube was of a conical form, and provided with two object-glasses of equal focal length, which were so adjusted as to admit of being moved in a direction transverse to the axis of the tube; or the object-glass was cut into two parts through a diameter, these two parts being relatively moveable. By this contrivance the two images which are formed in the focus of the eye-glass may be made to diverge, coincide or lap over each other, by merely varying the distance between the centres of the object-glasses, and this distance is indicated by a graduated scale attached to the tube. When the two images coincide, the angle subtended by the observed objects will be equal to that subtended by the centres of the object glasses, which being known, the magnitude of the observed object may readily be computed when its distance is given, or the distance determined when its magnitude is given. As this instrument does not differ in principle from the divided object glass micrometer, the reader is referred to the article Micrometer; and for further information relative to the invention, see the 'Mémoires de l'Académie Royale des Sciences,' 1748, p. 11. [Bouguer, in Biog. Div.] It is necessary, however, to refer to the noble instrument at Oxford, constructed by M. Repsold, and placed under the management of Professor Johnson. This heliometer is mounted as an Equatorial, with the hour-circle at the top of the pillar, and the declination circle at one end of the axis, both within reach of the observer. The divided object-glass is 7·5 inches in diameter, and has a focal length of 10·5 feet. It is cut into two semicircles by a section along a diameter, and the two pieces are made to slide along their common section by means of micrometer screws, connected with graduated scales. Rather than attempt to describe this instrument and the valuable work performed by it, which would be necessarily imperfect in our limited space, we think it best to refer to the 'Radcliffe Observations' for 1851, in which volume, and the previous one, the structure and use of the Oxford heliometer are ably discussed by Professor Johnson. There is also the celebrated memoir by Bessel in the 'Königsberg Observations,' and the dissertation by Brunow in his 'Späzische Astronomie.'

HE'LIOS (Ἥλιος), in the Greek, *Sol* in the Roman, mythology, the sun-god, was the son of Hyperion and Theia, or of Hyperion and Euryphaessa. Homer speaks of Helios as ascending the sky daily from Oceanus to give light to gods and men, and again descending by the western gate. Later writers enlarge much on the glory of his abode; or describe him as sailing during the hours of the night round half the globe in a vessel of gold, the gift of Hephæstus, and wrought by his hands, or softly sleeping on a golden couch. The chariot of Helios was a quadriga; his horses fed upon herbage growing in the blissful isles. By Homer, Helios is spoken of as seeing all that is done by men and gods, and hence he was able to give notice to Demeter of the abduction of her daughter Persephone, and to warn Hephæstus of Aphrodite's infidelity. His flocks were kept in the sacred isle of Thrinacia, in Sicily. Temples appear to have been erected to Helios in many parts of Greece; bulls, horses, goats, rams, and other animals, usually white, were sacrificed to him. Helios was especially honoured at Rhodes. Representations of him were engraven on the coins, both full-faced and in profile, surrounded with rays of light, or having streaming ray-like hair. The famous Colossus of Rhodes was a statue of Helios, 70 cubits high. In the later ages Helios was to a great extent confounded with Apollo.

HELIOSCOPE (a Greek term signifying literally "sun-observer") is a kind of telescope, adapted for making observations upon the sun without the eye being injured by the intense brightness of the solar rays. Dr. Hooke wrote a treatise in 1742 expressly on the subject of helioscopes, wherein he recommends four reflecting glasses to be so placed within the tube of the telescope that the solar rays may suffer four reflections before they strike the eye, and thus, he observes, their intensity will be reduced to the 256th part of their original intensity. Hevelius and other philosophers preferred the use of coloured glasses, which is the common practice of the present day; while Huygens merely blackened the inner side of the eye-glass by holding it over the smoke of a lamp or candle.

HELIOSTAT, an instrument used for making a solar beam appear stationary, or rather preserve an invariable direction, notwithstanding the motion of the sun in the heavens. Such an instrument is necessary to persons engaged in the higher branches of optical research, and its principle rests on that of the Equatorial. There is a reflecting surface connected with a polar axis, which is moved by clock-work at the rate of the sun's diurnal velocity, so that the ray thus reflected is constant in direction: whence the name of the instrument, from ἥλιος the sun, and *ἵστημι* to stand still. Of course the ray thus obtained may be received by a second mirror, and turned in any required direction. There is a good description of a heliostat in the second volume of Biot's 'Précis Elementaire de Physique,' also in Pouillet's 'Physique,' and Frick's 'Physikalische Technik.'

HELIOTROPE, an instrument used, chiefly abroad, in geodetic surveys, to enable the surveyor to transmit signals of reflected light from one station to another, and to perceive with facility the signals transmitted. M. Merz, of Munich, is said to have contrived the most convenient form of this instrument.

HELIX. [Screw.]

HELLEBORINE. A vegetable alkaloid of unknown composition contained in the root of the black hellebore. It resembles *piperine*.

HELLEBORUS NIGER (Black Hellebore, or Christmas Rose.) The root of *H. Niger* is now the officinal one, and it is to be regretted that many other roots, especially those of *Actæa spicata* and *Adonis vernalis*, are often intentionally or accidentally sold in its stead. These may be discriminated by physical characters (particularly the internal structure), and by chemical tests. The activity of hellebore seems to reside in its resinous matter, for which rectified (not proof) spirit is the proper menstruum.

Like most ranunculaceous plants hellebore can occasion rubefaction and inflammation of any surface with which it is brought in contact; when taken into the stomach in a moderate dose it gently stimulates it and the other viscera of the abdomen; but in large doses it is a fatal poison. It is a dangerous medicine, and one which is rarely necessary to have recourse to.

The hellebore of Hippocrates, Dioscorides, and other ancient writers, famous for the cure of insanity, is not the plant mentioned above, which is a native of southern Germany, the Apennines, also of Laconia and Mount Athos. The plant of the ancients is called by Dr. Sibthorp, *H. officinalis*, by Decandolle, *H. orientalis*; it is found on Mount Olympus, Helicon, and the island of Anticyra. Its purgative properties occasionally rendered it useful in madness.

HELLENENE. [Hellenin.]

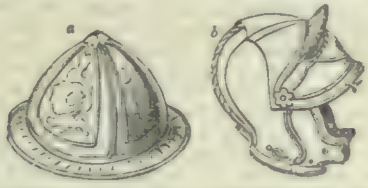
HELLENIN ($C_{42}H_{28}O_{6}$) is a concrete volatile principle, allied to the essential oils. It is a solid crystalline body, and is obtained from the *Inula Helenium*. With nitric acid it yields *nitro-hellenin*, whilst anhydrous phosphoric acid converts it into a hydrocarbon *hellenene* ($C_{36}H_{26}$).

HELM WIND. [Wind.]

HELMET, an ancient armour of defence for the head, still worn by the officers and soldiers of some of our cavalry regiments. Its original name was Helm, possibly borrowed from the Latin (of the lower age) *helmus*. Skinner however derives it from the Anglo-Saxon verb *helar*, to hide. "Helm" certainly occurs both in Cædmon's 'Paraphrase,' and in the Saxon Gospels, as well as in Ælfric's 'Glossary.' *Helmet* was probably adopted, in the middle age, from the Italian *elmetto*.

As a part of defensive armour the helmet is of high antiquity: some sort of covering of this description for the head appears to have been worn by the warriors of every country. Helmets were found even among the inhabitants of the South Sea Islands when discovered by Captain Cook. Among the oldest specimens now remaining are probably the two helmets found on the field of Cannæ in 1752, preserved in Sir William Hamilton's collection in the British Museum. Another ancient helmet, bearing an inscription, found at Olympia, was presented to the British Museum by King George IV.

The form of the Greek helmet and its general description may be collected from various passages of the Greek writers, from Homer downwards, and more especially from the medals and marbles on which it is represented. We give the representation of one from a terra-cotta in the Townley Collection in the British Museum, showing the heads of Athene and Zeus. In the same collection are others of Athene, and also one of Pericles. It does not appear that the Greek or Roman helmet usually protected the face. Both the helmets found at Cannæ, however, protected the face, and have projecting nasals. A helmet found at Pompeii (and now in the collection at Goodrich Court) has the nasal projection. Lipsius's treatise 'De Militia Romana' (iii., c. 5), contains a full account of the Roman helmet, with which the reader may compare the plates and descriptions in the third volume of Count de Caylus's 'Recueil d'Antiq.' For the helmets in more modern use, Grose's 'Treatise' and Meyrick's 'Critical Account of Ancient Armour' must be referred to. Among the varieties which had separate names we find the Chapelle de Fer, the Bacinet, the Burgonet, the Castle, the Hufken, the Morion, the Salade, and the Skull. These were almost invariably of steel. There was also the Justing Helmet, used in tournaments, which was sometimes of leather.



a, Morion ; *b*, Burgonet ; of the time of James I.

The *nasal*, the *ventaile* or moveable front, the *visor*, lifted up by pivots, and the *bevor*, to allow of drinking, were the names of parts of certain helmets introduced at different periods, and not always used.

As ornaments over the shield or coat of arms, helmets are still used in heraldry. The full-faced helmet with six bars, all of gold, damasked, is for the sovereign and princes of the blood; the full-faced helmet of steel for marquises and dukes; earls, viscounts, and barons have a profile or side-standing helmet of steel ornamented with bars; the full-faced helmet of steel, with the visor or bevor open, is for baronets and knights; the profile helmet, steel, with the visor closed, for an esquire.

HEMATEIN. [HEMATIN.]

HEMATIN ($C_{32}H_{14}O_{12}+2$ aq.), *hematoxylin*, the colouring-matter of the *Hæmatoxylon campechianum*, or logwood, discovered by Chevreul. It is prepared by evaporating a watery infusion of logwood to dryness, treating the residue with alcohol, filtering the spirituous solution, and evaporating it to the consistence of a syrup. If a certain quantity of water be added to this, and evaporation be performed with a gentle heat, the hematin crystallises, and requires only to be washed with a little alcohol and dried. Hematin crystallises in small laminæ of a reddish colour. The taste of hematin is at first sweet and astringent, and afterwards bitter. It is decomposed by heat. Water dissolves hematin, and the solution is of an orange-red, at 212° Fahr., but becomes yellow on cooling. Acids saturated with oxygen turn its colour first to yellow and afterwards to red; the alkalies in small quantity render hematin purple, and when in excess violet-blue, and eventually decomposing it, make it yellowish-brown. In contact with oxygen and alkalies hematin gives *hematein* ($C_{32}H_{12}O_{12}$), which unites with two equivalents of ammonia, forming a compound of a fine purple colour.

This colouring principle is a constituent part of all the colours prepared with logwood, and the changes which it undergoes by the action of acids and alkalies render it useful as a re-agent to detect their presence.

HEMATOCRYSTALLIN. A red crystalline albuminous matter found in blood under certain circumstances. It is soluble in acetic acid, but insoluble in potash. Ammonia dissolves it with the production of a peach-blossom colour. It contains, according to Lehmann,

Carbon	55·24
Hydrogen	7·12
Nitrogen	17·21
Sulphur	·21

HEMATOIDIN ($C_{14}H_9NO_3$?). A bright orange-red crystalline body formed in blood which has effused into the tissue of a living animal. These crystals are observed from the fourth to the twentieth day after the hæmorrhage. They are insoluble in water, alcohol, ether, and acetic acid, but dissolve in ammonia with a bright red tint, which soon becomes orange-yellow and finally brown.

HEMATOSIN ($C_{44}H_{22}N_3O_6Fe$?), the red colouring-matter of the blood; it has not however been obtained in a perfectly pure state, owing to the difficulty of separating it from other substances, and to the facility with which it undergoes change: when the coagulum of blood, which has been drained, is put into water, the colouring-matter dissolves and forms a fine crimson-coloured solution; this when exposed to a moderate heat dries and forms a brittle dark red substance, which is again soluble in water. When it has been acted upon by heat and alcohol it coagulates, owing to the albumen which it contains, and it is then insoluble in water, but soluble in potash; the red solution is rendered black by carbonic or sulphurous acid, but its colour is heightened by air on account of the oxygen which the latter contains; nitrous oxide renders it purple, and sulphuretted hydrogen greenish-black.

A peculiarity of hematosin is its containing iron, which does not occur in other parts of the animal system: when the clot of blood is decomposed by exposure to heat and air, the residue treated with hydrochloric acid exhibits by the usual tests the presence of peroxide of iron, unaccompanied by phosphoric acid. So also when dried blood is moistened with a little concentrated sulphuric acid, on the addition of water a solution is obtained which with ammonia yields a precipitate of peroxide of iron.

The hematosin of bullocks' blood, but not quite pure, for the reasons already stated, analysed by Mulder, yielded the following ingredients:—

Carbon	66·49	65·91
Azote	10·54	10·54
Hydrogen	5·30	5·37
Oxygen	11·01	11·75
Iron	6·66	6·58
	100·00	100·15

HEMATOXYLIN. [HEMATIN.]

HEMERALOPIA, a word which is now used to signify "night-blindness," though in fact it means "day-seeing," being similarly formed to the genuine Greek word "nyctalopia" (*νυκταλωπία*), which means "night-seeing." Much confusion has arisen in regard to the use of the two words, in consequence of an error committed either by Hippocrates or one of his early editors. In the second book of his 'Prædicta,' he says, "We call those nyctalopes who see by night;" but in the fourth and sixth books of his 'Epidemics,' the disease which he speaks of under a similar term appears to be that in which the patients are blind at night; and his translators, Paulus Ægineta, Ætius, and Galen, quote various authorities to show that those only are properly called nyctalopes who are affected with night-blindness. They have been followed by Bontius, Sir G. Blane, and many naval surgeons, who apply to the present disease the name of nyctalopia, or dysopia tenebrarum. Linnæus and Vogel however define nyctalopia to be night-vision, and call night-blindness, hemeralopia; and as their meanings have been since received by Scarpa, Lawrence, and all the chief writers on diseases of the eyes, they will be adopted here.

Night-blindness is a common disease amongst seamen in the East and West Indies, the Mediterranean, and in all hot countries, and affects in a slighter degree soldiers and the natives in the same parts of the globe. To persons affected by it, all objects appear at sunset as if covered with an ash-coloured veil, which becomes gradually denser, and at last involves them in complete darkness. In slight cases they can see by bright candle-light or by moon-light; but after the disease has lasted a few days, even the largest objects are invisible after sunset, and the patients have to grope their way even where the moon or candles are shining brightly. The disease will daily increase in severity if not judiciously treated, till the sight becomes weak by daylight, and so disordered that total blindness might be apprehended, though it very rarely follows. The pupils are generally dilated, and at night cannot be made to contract even by a brilliant light.

The most probable cause of this disease is the exhaustion of the retina, produced by the continued glare of a bright sun, either directly transmitted to it, or reflected from the clear waters of the tropical seas, or the bright sands of their shores; a condition of which one may form an idea from the inability to perceive objects in a dimly lighted room after leaving one where there was a glare of light. In many cases it is connected with a disordered condition of the digestive organs, and in others with scurvy.

The disease will generally get well, though it may exist for weeks or months. The most successful treatment is the repeated application of small blisters to the temples. Mr. Bampfield cured by this means upwards of 300 cases. This treatment never failed; but in some instances its effects were accelerated by the administration of purgatives and other medicines adapted for the coincident symptoms of scurvy or of disordered digestion. The best description of the disease is in Mr. Bampfield's 'Essay on Hemeralopia,' in the 5th vol. of the 'Medico-Chirurgical Transactions.'

Nyctalopia, night-vision, or day-blindness, probably never occurs as a separate disease. It is often a symptom of scrofulous ophthalmia and other diseases where the eye is so irritable that the stimulus of daylight cannot be borne, as well as of those conditions in which great dilatation of the pupil is requisite for vision, as in commencing cataract, or opacity of the centre of the lens or its capsule.

HEMIO'PIA (from ἡμί, "half," and ὤψ, "the eye") is a disease in which the patient sees only a part of the object he looks at; the middle of it, or its circumference, or its upper or lower part, or more commonly one lateral half, being completely obscured. In some cases it arises from a partial mechanical obstruction to vision, as when part of the transparent tissues of the eye become opaque, or when the upper eyelid falls over half the pupil. But more frequently it is the result of a morbid and partial insensibility of the retina, produced by the excessive stimulus of a bright light, and will cease after a night's rest; sometimes it is a consequence of disordered digestion; and sometimes a symptom of commencing amaurosis, or gutta serena, and terminates in complete blindness.

A very interesting account of this disease is given in the 'Philosophical Transactions,' for 1824, by Dr. Wollaston, who himself suffered from it on two occasions. He endeavoured to explain it by the semi-decussation of the optic nerves [EYE]; and it is remarkable that the appearances found in his brain after death were such as on that theory might have been anticipated. But in a large proportion of the cases the affection is too transient to admit of the supposition of any organic disease.

HEMIPINIC ACID ($C_{20}H_{10}O_{12}+4$ aq.) is formed by the higher oxidisement of opianic acid, one equivalent of which, by the addition of two equivalents of oxygen, gives rise to one equivalent of hemipinic acid; this addition is effected by heating either opianic acid or narcotine with dilute sulphuric acid and binoxide of lead, care being taken not to decompose the hemipinic acid as it is formed.

Hemipinic acid crystallises in colourless quadrilateral prisms. The crystals contain four equivalents of water, which are expelled below 212° Fahr. It has a slight taste, is soluble in water, melts in 356°, and sublimes like benzoic acid in shining laminæ. It is bibasic, and forms with ammonia a readily soluble and crystalline salt; with oxide of silver it forms an insoluble, white, pulverulent powder, the composition of which is represented by $C_{20}H_8O_{10}$, 2AgO.

HEPATITIS. [LIVER, DISEASES OF THE.]

HEPHÆSTUS (Ἥφαιστος) of the Greeks, Vulcánus of the Romans, the god of fire, especially so far as it manifests itself as one of the elementary powers of nature in volcanic districts, and so far as it is an indispensable means for the working in metal and prosecuting the pursuits of industry in general. According to Homer, Hephæstus was the son of Zeus and Hera, and was from his birth so weakly and ugly, that his mother, wishing to get rid of him, dropped him from Olympus. But Thetis and Eurynome, two marine divinities, received him falling, and with them he dwelled concealed for nine years, during which period he made various beautiful ornaments for the two goddesses. Whenever he remembered the cruel act of his mother, he felt indignant at her shameful treatment, and it was in revenge of this act that he made the golden chair, from which, when she sat in it, she was unable to rise, and from which he would not release her until Dionysus interceded for her; but otherwise he was kind and obedient to her, and on one occasion when he took her part against his father, Zeus seized him by the foot and hurled him from Olympus. He fell for a whole day, and came down on the island of Lemnos, where he was kindly received by the Sintians. He afterwards returned to Olympus, where he inhabited a palace built by himself, and which "immortal, starry, brazen," outvied the abodes of the other immortals ('Il.' xviii). Here he had his workshop with its anvil and twenty bellows which worked at his bidding, and he produced the most exquisite specimens of art both for gods and men. His wife is called in the 'Iliad' Charis, but in the 'Odyssey' it is Aphrodite, who however is faithless to him. She favoured Ares, and Hephæstus being informed of it by Helios (the Sun), caught the lovers together in a net, and called all the gods together to witness the spectacle. At the request of Poseidon, however, he liberated them. In the Trojan war Hephæstus sided with the Greeks, though he had a temple and priests at Troy also.

This is an outline of the story of Hephæstus, as far as it can be gathered from the Homeric poems. Other traditions mentioned by later writers state that he had no father, and that he was born of Hera without her having had any connection with a god or male being, in the same manner as Zeus gave birth to Athene. Others called Hephæstus a son of Talus, Coelus, Nilus, or Menanus, but these are foreign traditions transferred into Greece. Some legends describe Hephæstus as having become lame from his fall from Olympus upon the island of Lemnos, whereas according to Homer he was weak and lame from his birth. According to Virgil and other Latin writers, Vulcan does not produce his wonderful works of art alone, but is assisted by the Cyclopes, and his workshop is not in Olympus, but in some volcanic island. His favourite island was Lemnos, but other volcanic islands also, such as Lipara, Hiera, Imbros, and Mount Ætna in Sicily, are described as places in which he lived and worked. The ancient epic poets abound in descriptions of wondrous works of art said to have been made by Hephæstus. Like Athene, he is the divinity that gives skill to mortals, and teaches them the arts which gladden and adorn human life. That both divinities were looked upon as somewhat akin to each other, is clear not only from several legends, but also from the fact that at Athens they had common festivals and temples. The festivals celebrated at Athens in his honour were Hephaestia and Chalcia, the former of which was particularly splendid on account of the torch races (lampadephoria).

The worship of Hephæstus seems to belong to the oldest religious institutions of the ancient world, and undoubtedly arose from the worship of fire, so common among uncivilised nations and in the East. Later poets therefore, in applying the name of Hephæstus or Vulcan to fire in general, returned in some manner to the original idea of the god. In Samothrace, where remnants of the ancient Pelasgian religion continued to exist long after the introduction of the Hellenic religion into Greece, Hephæstus was the first among the Cabiri. In Etruria he was one of the twelve great national gods; and we find his worship established at Rome from the earliest times. A temple of Vulcan, situated close by the Comitium, is mentioned as early as the reign of Romulus and Tatius, and from the stories and rites connected with his worship at Rome, we must infer that his temple was viewed in a similar light to that of Vesta, that is, as a place of union, or the central point of the state.

The Fornacalia (from *fornax*, a furnace), which festival was celebrated at Rome on the 17th of February, was probably an ancient festival of Vulcan; his great festival, however, which was celebrated every year on the 23rd of August, with games in the Circus Flaminius, was in later times the great festival of the god. The Romans often dedicated to him the arms taken from an enemy: they were piled up and burnt. The Romans frequently designate Vulcan by the name Mulciber, which seems to have been given to him as a propitiating name, that he might not destroy the habitations and property of men by fire, but that he might be a beneficent and mild god, using his powers only to serve the human race. Hephæstus was not unfrequently represented in works of art, the most ancient of which seem to have been the dwarfish figures which were placed in private houses near the hearth. When art had reached a maturer state, he was represented as a man of full growth,—at first as of youthful form, later as a bearded and vigorous man. His most celebrated statue was that by Alcamenes at Athens, representing the god in a standing position, and slightly indicating his lameness. On vases and gems he is frequently figured in connection with Aphrodite; as revenging himself on Ares; working in his smithy, &c. His attributes are the instruments of the art of working in metal, as the hammer and the like, the Samothracian oval cap, and the chiton which leaves the right shoulder and arm uncovered.

(Jacobi, *Handwörterbuch der Griechisch. und Röm. Mythologie*, under 'Hephæstus;' Hartung, *Die Religion der Römer*, ii., p. 106, &c.; Hirt, *Mythologisches Bilderbuch*, p. 42, &c.; Müller, *Archäologie der Kunst*, §§ 366-8.)

HEPTYLENE. [ŒNANTHYLENE.]

HERA (Ἥρα) one of the twelve deities of the Greek Olympus, the Juno of the Roman Mythology, was the eldest daughter of Kronos and Rhea, the sister and wife of Zeus, the goddess of marriage and childbirth, and the protectress of married women. Her worship was of very great antiquity at Argos and throughout the whole of the Peloponnesus. The Samians, as well as the Spartans, are supposed to have derived their knowledge of this deity from Argos ('Paus.,' iii. 13; vii. 4); and the same is said to have been the case with the inhabitants of Epidaurus, Ægina, and Byzantium (Müller's 'Dorians,' i., p. 410, Eng. transl.). Her name also occurs in the early mythology of Corinth.

Although inferior in power to Zeus, Hera was treated with equal honour by the other Olympian deities. The Homeric poems contain but little of the mass of strange fiction attached to her in later times. She is represented in the 'Iliad' as jealous, obstinate, quarrelsome, and revengeful. Her disputes with her husband form a subject of frequent reference. At one time she even conspired with Athene and Poseidon to seize and bind the cloud-dispeller, but Thetis gave him warning, and with the aid of Briareus freed him from his bonds. ('Il.' i. 399.) It was then, perhaps, that Zeus inflicted on her the punishment he recals to her memory when angry with her for interfering against Hector and the Trojans; that, namely, of hanging her aloft in the sky, with her hands manacled, and two anvils fastened to her feet. ('Il.,' xv. 17, &c.) Hera seems always afterwards to have had a due dread of openly braving the anger of the father of the gods; but she was not afraid to gain her ends, however opposed to his, by subtlety, of which Homer records several instances. One of the most celebrated of her contrivances was the borrowing the cestus of Aphrodite, in order to stimulate the love of Zeus. ('Il.,' xiv.) But though Homer speaks much of the differences between them, he also shows that Zeus confided his inmost purposes to his wife, and that she always reckons on his confidence. The well-known story of her contention for the prize of beauty with Aphrodite and Athene was told to account for her active interference against the Trojans.

The marriage of Zeus and Hera forms a prominent feature in the worship of this goddess. As a truly married wife, and the wife of the greatest of the gods, Hera became the goddess of marriage and the married state. She was frequently represented veiled as a bride, and carried in processions, like a bride, on a car. By Zeus she had three children, Ares, Hephæstus, and Hebe.

The two most celebrated temples of Hera were at Argos and Samos; the latter was the largest temple with which Herodotus was acquainted. ('Herod.,' iii. 60.) The Samians themselves denied that their knowledge of this deity was derived from Argos, and asserted that she was born in Samos. ('Paus.,' vii. 4.) In many places she was associated in worship with Zeus.

Juno was worshipped at Rome with the epithets *Pronuba*, as presiding over marriage; *Lucina*, as bringing children to the light; *Regina*, as queen of heaven; and *Moneta*, as the warner, to whom a temple was erected on the spot where the house of Manlius Capitolinus stood. ('Liv.,' vii. 28.) The origin of the name *Moneta* is given by Cicero in his 'De Divinatione,' (i. 45). She was also styled *Virginalis* and *Matrona;* and the general festival held on the 1st of March in honour of her, and in which all women took part, was termed Matronalia.

The Greek artists, in accordance with the descriptions of the poets, represented Hera as a fully developed matron, yet as one who bathes in the fountain of virginity; of a perfectly beautiful form and features, but with pride and sternness as well as majesty marked on the countenance. The eyes are large (agreeing with Homer's frequent epithet, "Hera large-eyed, majestic"); the forehead fair and open, and with the braided hair brought down obliquely on either side. She is usually represented with a diadem (stephane), and often wears a veil. Her dress consists of a chiton and himation, the former of which leaves only her neck and arms bare. She often carries a sceptre, sometimes surmounted with a cuckoo; and is accompanied by her favourite bird the peacock. The famous chryselephantine colossal seated statue of Hera, in her temple at the foot of Mount Eubœa, in Argos, of which Polycletus was the sculptor, appears to have served as the type of the goddess for subsequent artists. There are few Greek statues remaining of the goddess of much importance; busts are numerous; we give a cut of a very beautiful one from the British Museum (First Græco-Roman Saloon). Representations of her on vases, gems, &c., are very numerous. The artistic idea of the Roman Juno followed close that of the Greek Hera.

Bust of Hera from the British Museum.

HERACLES (in Latin, *Hercules*), the most celebrated hero of Greek mythology, was the offspring of Zeus by Alcmene, daughter of Electryon, a son of Perseus, and king of Mycenæ. His reputed father was Amphitryon (son of Alcæus, another of the children of Perseus), who having accidentally killed his father-in-law Electryon, was compelled to leave Mycenæ, and take refuge in Thebes. Here Hercules was born and educated, and here his early feats of strength and valour were done; such as slaying the lion of Cithæron, delivering Thebes from the tribute to Erginus, king of Orchomenos, and taking in marriage the daughter of Creon. Most of his adventures were either immediately or remotely the result of the untiring hatred with which he was pursued by Hera. Even his famous twelve labours were the consequence of a sort of compromise entered into with Hera by Zeus, his constant protector, that he should undertake twelve great tasks which Eurystheus, as his master, should think fit to impose, the condition being that if he succeeded in them he should be raised to a place among the immortals in Olympus.

Being thus fated to serve Eurystheus, king of Mycenæ, he performed what are called his labours, in obedience to the commands of his master. They are so well known that we need only enumerate them:—the first was, to bring the skin of the Nemean lion; the second, to destroy the Hydra; the third, to catch the hind of Artemis; the fourth, to bring to Eurystheus the Erymanthian boar alive; the fifth, to cleanse the stables of Augeas; the sixth, to drive away the waterfowl of lake Stymphalis; the seventh, to fetch the Cretan bull; the eighth, to bring to Mycenæ the mares of Diomedes; the ninth, to obtain the girdle of Hippolyta, queen of the Amazons; the tenth, to bring the oxen of Geryon from the island of Erytheia; the eleventh, to bring the apples of the Hesperides; the twelfth, to conduct Cerberus from the under world. Almost innumerable other exploits were performed by him, such as the taking of Troy; the wounding of Hera; the conquest of the gigantes, &c., which are all related by the mythologists, Apollodorus, and others. But we cannot stay to relate them, as our object is rather to point out the classes to which these traditions belong, than to supply information which can be readily and much more suitably obtained elsewhere.

It will be enough to mention the manner of his death. Having to cross the river Euenus, Heracles swam over, leaving his wife to be ferried across by the centaur Nessus. But Nessus faithlessly attempted to ravish Deianeira, and Heracles turning back shot an arrow through his heart. The dying centaur bade Deianeira take some of his blood as a means for preserving the love of her husband. Afterwards when Heracles had been held long entranced with the charms of Omphale, and then leaving her went in quest of Iole, with whom he had become enamoured, Deianeira, fearing the entire loss of his affections, sent him a garment which she had steeped in the blood of Nessus. But the poison from the arrow of Heracles had contaminated the blood, and when the hero put on the garment he was seized with such terrible pains in every part of his body that, unable to bear the agony or to rid himself of the garment which clung to his flesh, he raised a lofty pile of wood on the summit of Mount Œta, and having commanded the shepherd Pœas to set fire to it, he placed himself on the top. Then Zeus caused a cloud to descend from heaven and amidst the pealing thunder, and flashing lightning, the hero was conveyed to Olympus.

There are then three distinct kinds of tradition relating to Heracles; the first consisting of stories drawn from some eastern or other religion, and applied to the Theban hero. Such are his wanderings round the coasts of Greece, which exhibit in a mythical form the establishment of the worship of a wandering god of the Phœnicians. Such also is his voluntary death on Mount Œta; and, according to Müller ('Dorians,' i. 444), his murdering his children. Another, and the second class of traditions, are those which represent him performing labours such as would naturally be those of a young community. (Pausan., viii. 14.) A third class exhibits him in the light of a conqueror and destroyer of tyrants, and here the awkwardness of ascribing the deeds of the Peloponnesian hero to the Theban Heracles is most striking; for while on the one hand he is serving Eurystheus as a slave, on the other he appears as one who forms alliances and disposes of kingdoms.

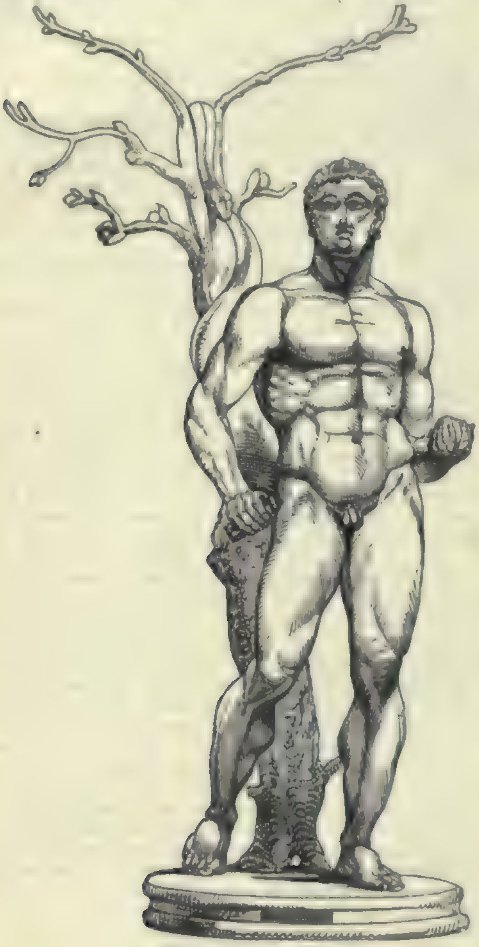
The legends of Heracles perhaps afford a better instance than those of any other hero or god, except Apollo, of the various sources from which mythical accounts spring.

Heracles was worshipped throughout Greece both as a god and a hero. His special oracle was at Bura in Achaia, the seat of the oldest of his temples. Bulls, boars, and rams were sacrificed, and hot springs were sacred to him. Women were not allowed to participate in his worship. At Rome there were two temples dedicated to Hercules.

Representations of Heracles are extremely numerous of almost every period of Greek and Græco-Roman art. In the archaic period the hero was clothed, and armed with spear and buckler, bow or sword; later, his only covering is the skin of the Nemæan lion, his weapon the huge club with which he killed the lion. Always he is figured as of enormous strength, with broad shoulders, large limbs, and muscles extremely developed. His person is noble, his countenance grave and earnest. The famous Farnese Hercules is the most celebrated ancient statue of the hero which has come down to us. It is inscribed with

Bust of Heracles from the British Museum.

the name of Glycon, and appears to be a copy of the Heracles of Lysippus: the hero is leaning on his club, and holds in his hands the apples of the Hesperides; the head of this statue is, however, a modern restoration, being copied from the magnificent colossal head now in the British Museum (Third Græco-Roman Saloon). Besides the many statues and busts of Heracles, in which he is figured from youth to age, there exist representations of him engaged in one or other of almost all the adventures related of him, from his birth to the pyre on Œta, in bronze and marble, groups and relievi; on vases, wall paintings, coins, gems, &c. We give cuts of a small bronze statue and the bust just mentioned; both the originals are in the British Museum. The bronze, which is in all 3 feet 5 inches high, the figure of the hero being 2 feet 6 inches high, was found in 1775, at Jebel, the site of the ancient Byblos, on the coast of Syria; it appears to be of the school of Lysippus, and may possibly be a work of the master himself.



Bronze Statue of Heracles.

The head, which is of colossal size, was dug up from under the lava at the foot of Mount Vesuvius, and presented to the British Museum by Sir William Hamilton.

(Müller's *Dorians*, and the authors whom he quotes; *Prolegomena; Archaölogie der Kunst*, and *Denkmäler der Alten Kunst;* Buttmann's *Mythologus;* and Thirlwall's and Grote's *Histories of Greece.*)

HERACLI'DÆ, the descendants of Heracles. According to tradition, after the death of Heracles his children took refuge in Attica, in order to escape the persecution of Eurystheus. They were hospitably received by Theseus, and with the assistance of the Athenians defeated Eurystheus. After the battle, the Heraclidæ are said to have obtained possession of the whole of Peloponneus; but they had not remained in the country long before a pestilence again drove them back to Attica. They attempted soon afterwards to march again into Peloponnesus, but were met at the Isthmus by an army consisting of Arcadians, Ionians, and Achæans. In a single battle with Echemus, king of Tegea, Hyllus, the eldest son of Heracles, was slain, and the Heraclidæ promised not to invade Peloponneus for a hundred years from that time. (Herod., ix. 26; Pausan., i. 41.) They did not, however, observe their engagement; for both Cleodæus, son of Hyllus, and his grandson Aristomachus, renewed the attempt, but without success. The Heraclidæ retreated to Doris, where they obtained a considerable army to assist them in the recovery of their dominions. With the aid of an Ætolian chief named Oxylus, they crossed from Naupactus to the southern side of the Corinthian Gulf eighty years after the Trojan war. (Thucyd., i. 12.) A battle took place between the Dorians under the command of the sons of Aristomachus and the Peloponnesians under that of Tisamenus, the grandson of Agamemnon, in which the latter were defeated, and all Peloponnesus, except Arcadia and Achæa, fell into the hands of the Heraclidæ. Elis was assigned to Oxylus, and the rest of the Peloponnesus was divided between the three sons of Aristomachus; Temenus obtained possession of Argos, Cresphontes of Messenia, and Aristodemus, or his sons Eurysthenes and Procles (for, according to the general tradition, Aristodemus did not live to enter Peloponnesus), of Lacedæmon. The land of the conquered country was divided among the Dorians, and the old inhabitants were obliged to emigrate, or were reduced to an inferior caste. (Pausan., ii. 18; iii. 1; iv. 3.)

Such is the traditional account of that important event in Grecian history, usually called "the return of the Heraclidæ," by which the Dorians obtained possession of the greater part of the Peloponnesus. It is asserted by the universal tradition of antiquity that the Dorians were led to this conquest by Achæan chiefs; but this fact has been doubted by many modern writers, who have considered it improbable that the Dorians should have been commanded by foreign chiefs. It has been supposed that the Heraclidæ were the hereditary princes of the Doric race, who were descended from a Dorian Heracles; and that the story of the Heraclidæ being descended from the Argive Heracles, who performed the commands of Eurystheus, was not invented till after the conquest of the Peloponnesus. (Muller's 'Dorians,' vol. i., p. 57, Eng. Transl.) Though the general tradition assigned the complete conquest of Peloponnesus to the sons of Aristomachus, it appears probable from other traditions that the greater part of the Peloponnesus was not reduced by the Dorians till long afterwards. (Thirlwall's 'Hist. of Greece,' vol. i.)

HERALD, an officer whose duty, during the middle ages, was to carry challenges or peaceful messages from one sovereign or nobleman to another, to proclaim peace or war, to lay out the lists in jousts or tournaments, to be witness of all combats whether general or particular, and to record in writing the names of those who behaved most valiantly, to number the dead after battle, and specially to supervise all matters connected with the bearing of coat-armour, the marshalling of processions, and other state ceremonies. His functions were something like those of the Greek *kerux* (κήρυξ), and the Roman *Fecialis;* but the origin of the name is much disputed, and the actual date of the institution uncertain. The word *Heraldus* occurs in the imperial constitutions of Frederick Barbarossa, in 1152, about the same time to which the origin of heraldry is with most reason assigned. The earliest mention as yet discovered, of a herald in England is in a pell-roll of the 12th of Edward III.; but there is little doubt that the office existed as early at least as the dawn of hereditary coat-armour. The English heralds were first incorporated by Richard III. [HERALDS' COLLEGE.] There are three orders or grades of heralds, namely, kings of or at arms, heralds, and pursuivants. They were anciently created with much ceremony, and the mode is curiously detailed by Gerard Legh apud Upton. "It is necessary," says he, "that all estates should have couriers as their messengers for the expedition of their business, whose office is to pass and repass on foot, being clad in their prince's colours 'parted upright;' that is to say, half of one colour and half of another, with the arms of their sovereigns painted on the boxes in which they carried their despatches, and which were fixed to their girdle on the left side. It was not permitted to them to bear the arms of their lord in any other manner." "They were knights," he adds, "in their offices, but not nobles, and were called knights-caligate of arms, because they wore 'startuppes' (a sort of boot or gaiter) to the middle leg." "When they had conducted themselves properly in this situation for seven years, they were made chevaliers of arms, and rode on horseback to deliver their sovereign's messages, clad in one colour, their garments being only guarded or trimmed with the colours of their sovereign, and bearing their boxes aforesaid, with the arms painted on them, on the left shoulder, 'and not elsewhere.'" From these runners and riders the three orders of heralds were supplied, the chevalier of arms, having served another seven years, being created a pursuivant in the following manner:—The herald of the province, to whom he was to be pursuivant, wearing his coat of arms, took the candidate by his left hand, holding in his right a cup of silver, filled with wine and water, and leading him to his sovereign, in the presence of many witnesses duly summoned for this purpose, inquired by what name the pursuivant was to be created; and upon the sovereign's answer proclaimed his style accordingly, pouring some of the wine and water upon his bare head. He then invested him with the tabard, or herald's coat, emblazoned with the arms of the sovereign, but so that the sleeves hung upon his breast and back, and the front and hind parts of the tabard over his arms, in which curious fashion he was to wear it till he became a herald. Strutt has given a representation of the pursuivant so attired from the Harleian MS. 2278, without being aware of the distinction. The oath of office was then administered to him, and lastly the sovereign presented him with the silver cup aforesaid. Having once been made pursuivant, he might be created a herald, "even the next day," which was done by the principal herald or king of arms leading him in like manner before the sovereign, but bearing a gilt instead of a silver cup, and turning the tabard so that the sleeves hung in their proper place over the arms.

A collar of SS was then put about his neck, one S being argent, or silver, the other sable, or black, alternately, and when he was named, the prince himself poured the wine and water on his head, and after the oath was administered gave him the cup as before; whereupon the herald cried, "A largess." The kings of arms were created and solemnly crowned by the sovereigns themselves, and distinguished from the heralds by richer tabards, the embroidery being on velvet instead of satin, gilt collars of SS, and coronets composed of a plain circle of gold surmounted by sixteen strawberry leaves, eight of which are higher than the rest.

Modern heralds of all classes in the British dominions are now with some few exceptions, made and appointed by the hereditary earl marshal, and their functions and privileges are much abridged and disregarded. The present number in England is fourteen, namely: four kings of arms—Garter, Clarenceux, Norroy, and Bath; the second and third being provincial kings, Clarenceux having power over all parts of England south of the Trent, and Norroy over all parts north of it. The fourth is specially attached to the Order of the Bath, and is not a member of the College of Arms. Six heralds—Somerset, Chester, Windsor, Richmond, Lancaster, and York; and four pursuivants Rouge Dragon, Portcullis, Blue Mantle, and Rouge Croix. In Scotland there is one king at arms named Lyon; and in Ireland one, named Ulster. There is also a king of arms of the order of St. Michael and St. George in the Ionian Islands. To these regular officers are sometimes added, by command of the king to the earl marshal, a herald or pursuivant extraordinary. Such were the heralds Arundel, Norfolk, and Mowbray; and on the occasion of the funeral of the late King William IV., Mr. Albert Woods, now Lancaster herald, son of Sir W. Woods, then Clarenceux king of arms, was created pursuivant extraordinary.

HERALDS' COLLEGE, or COLLEGE OF ARMS, a corporation founded by Richard III. in the first year of his reign by a charter dated the 2nd of March, 1483, in which he gives to the principal officers of the corporation a house called Colde Arbor, in the parish of All Hallows the Less, London. In the first year of the reign of Henry VII. this house was seized into the king's hands under the Act of Resumption as the personal property of John Writhe, then garter king of arms; and during the reign of that king and of his successor Henry VIII. the heralds made several unsuccessful attempts by petition to obtain a restoration of it, or the grant of some other building for their general use. King Edward VI., in the third year of his reign, by a charter dated June 4th, confirmed to them all their ancient privileges; and Philip and Mary, by charter of the 18th of July, 1554, re-incorporated them, and granted to them Derby House, then occupying the site of the present college on Benet's Hill, near St. Paul's Churchyard. The old building was destroyed in the great fire of London; but all the books, papers, &c., were fortunately saved, and removed to the palace in Westminster, where the heralds held their chapters, &c., until the college was rebuilt. The corporation consists of three kings of arms,—Garter, Clarenceux, and Norroy (Bath not being a member),—six heralds, and four pursuivants. [HERALD.[The arms of the college are—argent, a cross gules between four doves rising azure. Crest, on a ducal coronet, Or, a dove rising azure. Supporters, two lions rampant gardant argent, ducally gorged Or. There is a heralds' college in Scotland, composed of Lyon king of arms, six heralds, and six pursuivants.

HERALDRY, the art of arranging and explaining in proper terms all that appertains to the bearing of coats of arms, badges, and other hereditary or assumed marks of honour; also the science of marshalling processions and conducting the ceremonies of coronations, instalments, creations of peers, funerals, marriages, and all other public solemnities.

The origin of heraldry, in the first and most commonly understood sense, has been attributed by the general consent of all rational writers on the subject, to the necessity for distinguishing by some outward sign, amidst the confusion of battle, the principal leaders during the expeditions for the recovery of the Holy Land. But nothing is absolutely known concerning it beyond the fact that the middle of the 12th century is the earliest period to which the bearing of heraldic devices, properly so called, can be traced, and the commencement of the 13th, the time about which they became hereditary.

The earliest roll of arms of which we have any notice is of the reign of Henry III.; and the reign of Edward I. presents us with the earliest heraldic document extant. The famous roll of Caerlaveroch, a poem in old Norman French, rehearses the names and armorial ensigns of all the barons, knights, &c., who attended Edward I. at the siege of Caerlaveroch Castle in 1300. [BANNER.] Heraldry is therein first presented to us as a science. The principal rules and terms of the art were then in existence, and from about that time the latter are continually found in the fabliaux and romances of France and England.

The oldest writer on heraldry whose work has descended to us is Nicholas Upton, whose treatise 'De Militari Officio' was composed in the reign of Henry V., and translated in that of his successor by Juliana Barnes [BERNERS, in BIOG. DIV.], in the work known as the "Boke of St. Alban's." As Upton quotes no earlier authorities, his definitions and explanations can only be looked upon as assertions made nearly three hundred years after the origin of the practice, and, consequently, to be believed or not, according to the discretion of the reader. In the reign of Richard III. the English heralds were incorporated and the College of Arms founded; and in the following century a swarm of writers arose both in France and England, each contradicting the other, and wasting a world of learning and research in the most absurd and idle controversies.

On the decline of chivalry the study of heraldry became gradually neglected, and the art, which had formed for centuries a portion of the education of princes, and occupied the attention of some of the most learned men in Europe, was abandoned to the coach-painter and the undertaker, while kings of arms and pursuivants were looked upon as mere appendages of state pageantry, their office ridiculed, and their authority defied.

That the pedantic nonsense of such writers as Morgan, Ferne, Mackenzie, &c., contributed to these results, there can be little doubt. A taste for the critical study of antiquities generally is now, however, reviving throughout Europe, and the use of heraldry as a key to history and biography is daily becoming more and more acknowledged.

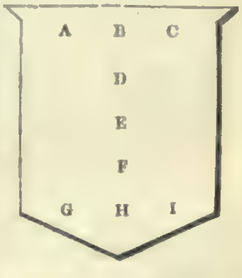
The rules of heraldry, as now practised at the College of Arms, are, as we have before remarked, comparatively modern, and vary in some points from those observed in France and Germany.

According to the received authorities, there are ten classes of arms, namely:—

1. Arms of *Dominion*, being those which sovereigns bear as annexed to the territories they govern.
2. Of *Pretension*, those borne by sovereigns who are not in possession of the dominions to which such arms belong, but who claim or pretend to have a right to such possession; as, for instance, the kings of England from Edward III. to George III. quartered the arms of France.
3. Arms of *Community*, being those of bishoprics, cities, universities, academies, and other bodies corporate.
4. Of *Assumption*, such as are assumed by a man of his proper right without the grant of his sovereign, or of a king at arms; as, for instance, when a man of any degree whatsoever has taken prisoner in lawful war any gentleman, nobleman, or prince, he may bear the arms of that prisoner, and transmit them to his heirs for ever.
5. Arms of *Patronage*, such as governors of provinces, lords of manors, patrons of benefices, &c., add to their family arms, as a token of their superiority, rights, and jurisdiction.
6. Arms of *Succession*, borne by those who inherit certain estates, manors, &c., either by will, entail, or donation.
7. Arms of *Alliance*, such as the issue of heiresses take up to show their maternal descent.
8. Arms of *Adoption*, borne by a stranger in blood, with the special permission of the sovereign, applied for in order to fulfil the will of the testator who may bequeath certain moneys or estates on condition of the party's assuming his name and arms.
9. Arms of *Concession*, augmentations granted by the sovereign of part of his own ensigns or regalia to such persons as he pleases to honour therewith.
10. Arms *Paternal* and *Hereditary*, such as are transmitted from the first possessor to his son, grandson, great-grandson, &c.; thereby forming complete and perfect nobility. The son being a gentleman of second coat-armour, the grandson a gentleman of blood, and the great-grandson a gentleman of ancestry.

These several sorts of arms are displayed on shields, or escutcheons, and on banners, the ground of either being called the field, and the figures borne upon it the ordinaries and charges.

The shield, or escutcheon, contains certain points or locations, namely, A, B, C, the chief: A being the dexter or right-hand chief, B the precise middle chief, and C the sinister or left-hand chief. D is the honour point; E the fess point, being the exact middle of the shield; F the nombril or navel point; G, H, I, the dexter, middle, and sinister base points.



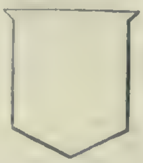
The colours of the escutcheon, or of its ordinaries and charges, are five:—

Red	(the heraldic name of which is) . .	Gules.
Blue	„ „ . . .	Azure.
Black	„ „ . .	Sable.
Green	„ „ . . .	Vert.
Purple	„ „ . .	Purpure.

To which must be added, or rather prefixed, *yellow* and *white*, which being ordinarily represented by gold and silver, are called *metals*, and named by heralds, after the French, *Or* and *Argent*.

There are also two other colours recognised by heralds, but rarely seen in English coats of arms, namely, orange, called *Tenne*, and a dark blood-red inclining to purple, called *Sanguine*, or *Murrey*, from mulberry. These colours and metals have been since the 16th century expressed in engravings by lines and points or dots, the ingenious idea of which is attributed to an Italian named Petrasancta. Thus *Or*, or *gold*, is known by the escutcheon being filled with small points or dots.

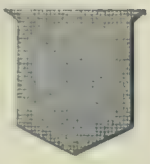
Argent, or *silver*, by the shield being left perfectly plain.



Gules, or *red*, by perpendicular lines from the top to the bottom of the escutcheon.

Azure, or *blue*, by horizontal lines.

Sable, or *black*, by the two former crossing each other.



Vert, or *green*, by diagonal lines from right to left.

Purpure, or *purple*, by similar lines from left to right.

Tenne, or *orange*, by perpendicular lines crossing lines from right to left.

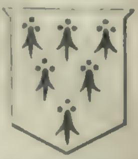
Sanguine, or *murrey*, by transverse lines from each side of the shield.

The metals and colours above mentioned are also distinguished by some heralds by the names of planets and precious stones; and there are besides, according to Sir John Ferne ('Glory of Generosity') twelve other fantastical sorts of blazoning (by which word is meant, describing in proper heraldic terms, the bearings, &c., of a shield or banner); but as all these are now obsolete, we shall only allude to the fact without encumbering our columns by rehearsing them.

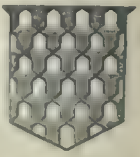
There are nine roundlets, or balls, also used in heraldry, the names of which are sufficient to denote their colour, without particularising the same, namely :—

Bezants .	. Or.	Hurts .	. Azure.	Pellets	. Sable.
Plates .	. Argent.	Pommes	. Vert.	Oranges	. Tenne.
Torteaux	. Gules.	Golpes	. Purple.	Guzes	. Sanguine.

To metals and colours must be added FURS, which, according to some heralds, are of ten different sorts. Those most commonly met with are however comprised under the names of Ermine and Vair, the rest being variations of colour and disposition. The first is represented in heraldry thus, the field being *white*, or *argent*, the spots and tails *black*, or *sable*.



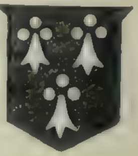
The second is represented by figures like little cups or bells reversed and ranged in lines, thus: the colours being, of the field *Argent*, of the cups *Azure*, or vice versâ; but where the matter is doubtful, the metal to possess the field by pre-eminence.



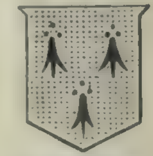
N.B. If the same figures are found in other colours, they are no longer to be blazoned or described as *Vair*; but "*Vairy, Or*, and *Gules*," or whatever else it may be.

The principal variations above mentioned are :—

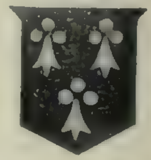
1. *Ermines*, the field of which is *Sable*, and the spots and tails *Argent*.



2. *Erminois*, the field *Or*, the spots and tails *Sable*.

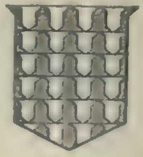


3. Pean, the field *Sable*, the spots and tails *Or*.

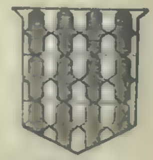


4. *Erminites*, the same as Ermine, with the addition of a *red* hair on each side the *black* tails.

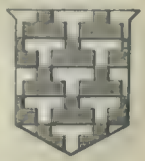
5. *Vair en point* is when the point of a cup or bell is opposite to the base of another.



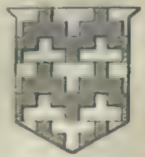
6. *Counter Vair*, when bells of the same colour are placed base to base and point to point.



7. *Potent* is classed as a fur, but the word signifies a crutch or a gibbet (*Potence*, Fr.). It is represented thus—

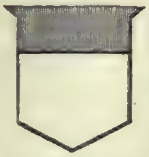


8. *Potent-counter-potent*, sometimes called *Vairy cuppy*, is when the crutches are counter placed; thus—

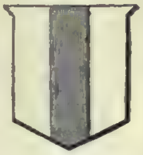


The principal charges or figures expressed on the shield are called the *Ordinaries*; they are nine in number, and styled *honourable*. They consist of the *Chief*, the *Pale*, the *Bend*, the *Bend Sinister*, the *Fess*, the *Bar*, the *Chevron*, the *Cross*, and the *Saltier*.

The *Chief* is the upper third of the escutcheon, determined by a horizontal line; thus—

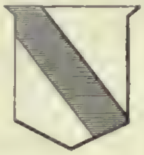


The *Pale* is the middle third of the field when divided perpendicularly.



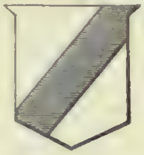
This ordinary has two diminutives; the *Pallet* being half the width of the *Pale*, and the *Endorse* half that of the *Pallet*.

The *Bend* is formed by two diagonal lines drawn from the right or dexter chief to the left or sinister base; thus—

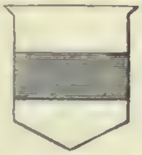


The *Bend* has four diminutives; the *Bendlet*, the *Garter*, the *Cost*, and the *Ribbon*.

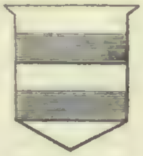
The *Bend Sinister* passes from the left to the right of the shield, and has two diminutives, the *Scarp* and the *Baton*.



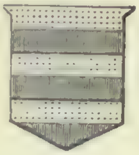
The *Fess* occupies the middle third of the shield divided horizontally.



The *Bar* is similarly formed, but occupies only a fifth of the shield, and is never borne single.

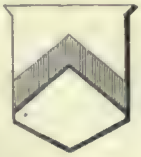


When the number exceeds five, it is blazoned Barry of so many pieces, expressing the number and colour, as Barry of Six, Or, and Gules.

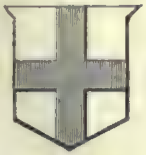


The *Bar* has two diminutives; the *Barrulet*, half the width of the *Bar*; and the *Closet*, half that of the *Barrulet*.

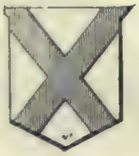
The *Chevron* is a figure formed like the rafters which support the roof of a house, and is therefore sometimes called *a Spar*, and in German *Sparren*. It has two diminutives, the *Chevronel* and the *Couple-close*.



The Cross, as an ordinary, is drawn thus. All other sorts of crosses should, in our opinion, come under the head of common charges, as they must be specially described.



The *Saltier* is *the figure generally* known in England as St. Andrew's Cross, and is indeed always so called by the German heralds, and frequently by the Scotch.



Eight of these nine honourable ordinaries give their names to the various single lines used in dividing the field of the escutcheon, where more than one metal or colour is required, such escutcheon being described as *parted per pale*, when divided perpendicularly; *per fess*, when divided horizontally; *per cross*, when in four squares; *per saltier*, when in four triangles; *per bend*, when diagonally, from right to left; *per bend sinister*, when in the contrary direction; and *per chevron*, when in the shape of that figure. The Chief being itself formed by a single line, they do not say *parted per chief*: but when the partition-line is not straight or even, its peculiarity must be specified in every instance: and of crooked lines there are eight recognised by English heralds, namely :—

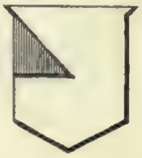
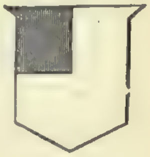
1. Engrailed . . .	2. Invected	3. Wavy	4. Embattled	5. Nebuly	6. Raguly	7. Indented	8. Dancette, limited to three indentations.	
It is therefore necessary to say 'a Chief engrailed,' or 'a Cross invected,' or 'Parted per fess, indented,' and so forth.

In addition to the nine honourable ordinaries are to be mentioned the subordinate ordinaries, the Gyron, the Quarter, the Canton, the Fret, the Pile, the Orle, the Tressure, the Flanches, the Flasques, the Voiders, and, according to some authorities, the Lozenge, the Fusil, the Mascle, and the Rustre.

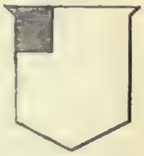
The Gyron is formed thus: and when the shield is divided per cross and per saltier into eight similar divisions, it is called Gyronry.



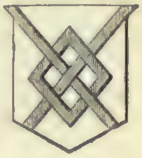
The Quarter is, as its name imports, the fourth part of the shield, and is always placed in chief.



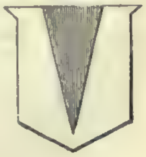
The Canton is a square figure like the quarter, but smaller, occupying only a third part of the chief itself.



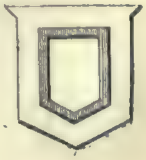
The Fret is formed thus: when composed of more pieces similarly interlaced, the field is said to be *fretty*.



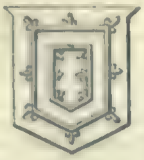
The Pile is formed like a wedge, thus: it is sometimes borne *in bend*, but must then be so described.



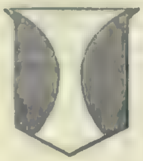
The Orle is a sort of border or frame within the shield.



The Tressure is commonly supposed to be half the breadth of the Orle, and is generally borne double, and what is called fleury and counter-fleury, as in the royal achievement of Scotland.

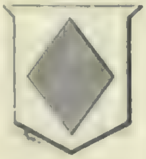


The Flanches are formed by two curved lines nearly meeting in the centre, thus:

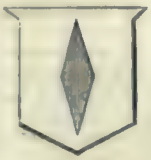


The Flasques may be called the diminutives of the Flanches, and the Voiders the diminutives of the Flasques, as the only difference is in the quantity of the shield which they occupy.

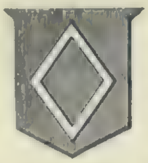
The Lozenge is of the shape of the Diamond in a playing-card. A shield so divided by diagonal lines as to form several of such figures is called Lozengy.



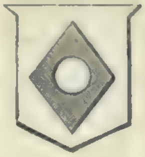
The Fusil, called also a Spindle, is longer and narrower than the Lozenge. A shield so divided by lines as to form several of such figures is called Fusily; and if parted per pale and per bend, would be either Lozengy-bendy or Fusily-bendy, according to the width of the space between the lines.



The Mascle is of the same form as the Lozenge; but hollowed out, or, in heraldic term, *Voided*, so as form a mere frame of that shape.

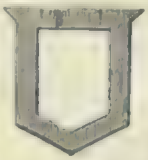


The Rustre is a similar figure, but pierced or voided round, instead of square, thus:



To these some heralds add the Inescutcheon, which is a small shield placed in the centre or top point of the escutcheon; but this, except when borne as an escutcheon of pretence, may, in our opinion, be ranked amongst the common charges, as may also the lozenge, the fusil, the mascle, and the rustre.

We have next to speak of *differences*, so called from their being particular marks borne to distinguish persons of the same family from one another. While heraldry was arbitrary, the son frequently assumed arms perfectly different from those of his father; but in the time of Edward I. we find two marks generally considered as family differences or signs of cadency,—the *Border* and the *Label*.



The Border is, as its name denotes, a guard or edging to the shield, and by the French heralds is accounted an ordinary. The border should always be in width one-fifth of the breadth of the shield itself, and stops when it encounters a chief, a quarter, or a canton, but passes over all other ordinaries. If the interior line is not plain or even, it must be described as *engrailed*, *invected*, &c. When divided into four equal parts, it is called a *border quarterly*. When divided into small squares of different colours, it is called a border *gobonated*, or *gobony*, or *compony*. When in *two* rows of squares, it is called a *border counter-compony*. When into *three* rows of squares, it is called *checky*.

The Label, or File, as it is sometimes called, is a sort of fillet from which depend generally three or five lambeaux, or points, thus,

It is sometimes however said to have been borne as a common charge, and is to be found only with one point and with as many as nine: other authorities consider it always as a *difference*. The label of three points is now always used as the difference of the heir or eldest son of the first house.

For the second son the difference is a crescent . .

For the third, a mullet, or star of five points . .

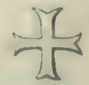
For the fourth, a martlet . . . . . .

For the fifth, an annulet . . . .

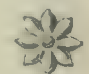
For the sixth, a fleur-de-lys . . . . . .

For the seventh, a rose . . . . . .

For the eighth, a cross moline . . . . . .



For the ninth, a double quaterfoil . . . .



These are called the differences of the first house; and by the six first, the six sons of Thomas Beauchamp, earl of Warwick (temp. Edward III.) are distinguished in a window of St. Mary's Church at Warwick.

The children of the second house are distinguished by the first son bearing a crescent charged with a label: the second, a crescent charged with a crescent; the third, a crescent charged with a martlet, and so on.

The junior branches of the royal family are however distinguished by the label only, the Prince of Wales bearing it simply argent, and the rest differenced by various charges, a practice as ancient as the reign of Richard II.

In the general term *charges* we comprise all descriptions of figures borne in coat-armour, whether things animate or inanimate, real or imaginary, everything in short contained in or placed upon the shield; but those we have above-mentioned are to be distinguished from the *common charges*, by which expressions are understood all other.

Many of these, such as crosses and crosslets in all their variety, escalop shells, bezants (the golden coins of Byzantium, or Constantinople), Saracens' heads, &c., were assumed during the Crusades, or after the return of the Crusaders, by themselves or their families, in commemoration of those expeditions. Others, such as beasts, birds, fishes, reptiles, trees, flowers, the sun, moon, stars, &c., were borne either as types of the peculiar dispositions or qualities, or as denoting by some similarity of sound in the pronunciation the names of the bearers. Such have been called with us *canting* or *punning* arms, and by the French *armes parlantes*. It has been the fashion with modern heralds to decry this species of bearing; to account it of rare occurrence in ancient heraldry, and less honourable where it did occur: but recent investigations prove it to have been one of the most frequent as well as most ancient descriptions of charges, and as worthy of respect as any other. It has indeed been suggested that the bearing frequently gave rise to the surname itself. This is however a mere conjecture; but the grants of arms which have been handed down to us prove incontestably that when sovereigns desired to express their approbation of noble or useful deeds by such distinctions, the name of the person to be honoured was frequently expressed by the charge, instead of the act he had performed, which would never have been the case had it been considered in those days as an inferior bearing. An acquaintance also with the language of the nation and time in which the arms were first granted or assumed, as also of its pronunciation, is of the greatest importance to this question, and such researches may yet shed much light upon the origin and history of heraldry. The Cornish family of Godolphin bear a white eagle; but those who are unacquainted with the ancient Cornish language would be far from guessing that a white eagle was called in that language, *Godolcan*, a very near approach to the name of the bearer. A third species of allusive bearings is that which designates the place or office of the individual; and many charges appear in the arms of our nobility derived from ancestors who have held situations of high honour or great trust under our early monarchs; and lastly, a fourth portion have been assumed, as Camden has exemplified, in honour of the feudal lord, or most powerful neighbouring chief, or been conceded to the bearer by such nobleman as a mark of respect or affection.

The crest is the next object in point of antiquity to the shield. It was the ornament worn upon the helmet, and consequently the helmet itself was generally represented with it upon the seal of the knight or nobleman. The crest from Richard II.'s time was rarely worn, except upon the tilting helmet, and then upon a wreath which was generally a twisted roll of silk of two colours, being those of the family of the wearer. Beneath this wreath was frequently worn, as a sort of hood to the helmet, a piece of silk or velvet lined with ermine, which floated with jagged ends on the shoulders: these are by the French called *hachemens*, and by us *mantlings* or *lambrequins*. *Supporters* are of later origin, and are supposed to have taken their rise from the fanciful devices of the early seal-engravers, who filled up the space not occupied by the shield with all sorts of monsters or natural animals, by way of ornament. They did not become common till the close of the fourteenth century, and Henry VIII. was the first monarch who formally granted supporters to peers of the realm and knights of the garter and of the bath. No person under the rank of a knight of the bath has a right to supporters, unless by special grant of the sovereign.

Mottoes had their origin probably in the war-cries of the different knights. There are several instances however of a motto being borne in addition to the *cri de guerre*.

The badge or device is frequently confounded with the crest; but it was altogether independent of the armorial bearings of the family, although in many instances it became hereditary. It is frequently, but very incorrectly, placed upon a wreath.

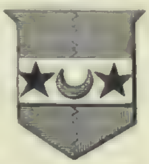
The arrangement and description of all the above insignia in proper heraldic order and terms are styled the *marshalling* and *blazoning* of arms.

We shall speak first of *blazoning*. The verb "to blazon" is generally derived from the German *blasen*, to blow or sound a horn or trumpet, such being usually the practice before proclaiming the style or arms of any personage on his arrival in the camp, the lists, or the banqueting hall. The term however was soon applied to the proclamation itself, and finally used as synonymous with description generally: thus we find in the old book on hunting written by Jacques de Fouilloux, and presented to Charles IX. of France, the description of the hare entitled 'Le Blason du Lièvre.' To spread the fame or the disgrace of any person was also to blazon it. Favine, in his 'Théâtre d'Honneur,' says, "Les habitans disent pour blasonner leur ville;" and in the Chronicle of Louis I., duke of Bourbon, the knights of the order of the crown are commanded not to suffer any person to defame (blazonner et medire) the ladies.

The principal rules of blazoning are as follows:—

1. In blazoning a coat the herald begins with the field, noticing the lines, if any, by which it is divided, the difference of those lines, and then the colours, next the charges, beginning with the *immediate* charge, that is, the one which lieth nearest the field, such as any ordinary, and nearest the centre of the field if a common charge, and lastly, the more remote or inferior charges.

Thus the accompanying coat would be blazoned: *Party per pale, indented, azure, and gules; on a fess argent, a crescent of the first between two mullets sable.*



2. All tautology is to be strictly avoided, and the repetition particularly of such words as *of*, *or*, and *with*, is considered a great fault. In the above blazon, "a crescent of the *first*" is said, in order to avoid the repetition of the word *azure*; so, if it were gules, we should say "a crescent of *the second*." For the same reason, when the field is undivided, and the charges, though of more than one description, of only one colour or metal, it would be blazoned in this way: "Argent, a chevron between three mullets sable," by which the chevron is understood to be sable as well as the mullets.

3. It is accounted by English heralds false heraldry to put metal upon metal, or colour upon colour; but instances of such blazoning frequently occur in foreign arms, particularly in those of German families. The objection is notwithstanding a sound one, as the charges should be rendered as distinct as possible, which can only be done by adhering to the English rule.

4. When a charge is represented of its *natural* colour, it is to be blazoned *proper*.

5. In blazoning animals, the teeth and claws, or talons, of the ravenous beasts are called their arms; and when they are to be represented of a different colour or metal from that of their bodies, they must be blazoned as "*armed*, Or," or "Gules," as the case may be. If the tongue is shown the beast is said to be langued of such or such a colour, as "a Lion, argent, *armed* and *langued*, azure." More docile animals, the stag and deer, for instance, are said to be "attired," and not "armed." Beasts of prey are, according to their attitude, blazoned, *Rampant*, *Rampant-guardant*, *Rampant-regardant*, *statant*, *passant*, *salient*, *sejant*, *couchant*, *dormant*, *naissant*, *issuant*, *combattant*, *endorsed*, *erased*, &c. Stags are said to be *trippant*, *at gaze*, &c.

Birds of prey are also blazoned as "armed" of such a colour, but such as have no talons are described as "beaked and membered." *The Cock* is said to be *armed*, *crested*, and *jelloped*, the latter term referring to the wattles, or gills.

Birds, according to their attitudes, are blazoned *Volant*, *Displayed*, *Preying*, &c.

Fish, when placed horizontally, are termed "*naiant*;" when perpendicularly, "*hauriant*;" when *bent* (as the dolphin is generally represented), "*embowed*;" if face to face, "*respecting each other*;" if back to back, "*endorsed*."

The sun must be blazoned according to his condition, full, or in his eclipse. The moon, defined as crescent, *in*crescent, or *de*crescent: the first being, when represented with the horns upwards; the second, when the horns point to the dexter or right side of the shield; and the third, when to the left or sinister side. If downwards, it is called a *crescent reversed*.

The human figure is blazoned either *vested* or *naked*. Parts of the human figure, if cut off, are said to be *couped*; if ragged or torn off, *erased*. Heads are also blazoned *wreathed* or *banded*, as the case may be.

Flowers are blazoned *jessant*, *slipped*, *seeded*, &c.

When the field of an escutcheon is covered with flowers of the same colour or metal, or any other pattern with flowers or scroll work intermixed, it is said to be *diapered*; but when it is filled with flowers, crosses, or any other device of another colour or metal, repeated, as the French say, *sans nombre*, it is then blazoned as *semée*. An animal so covered with flowers or crosses should be blazoned as *powdered*. When the field, charge, or supporter is covered with *goutes*, or *drops*, it is called *gutty*; and if of gold or yellow, *gutty d'or*; of argent *gutty d'eau*; of gules, *gutty de sang*; of azure, *gutty de larmes*; of vert, *gutty de vert*; and of sable, *gutty de poix*. When a bend, fess, or any other ordinary passes over an animal, the animal is said to be *debruised*. When the charge is divided by any of the partition lines, and the colours of the field are reversed upon it, it is said to be *counterchanged*.

By *marshalling* of arms we understand the orderly disposition of sundry coats, belonging to distinct families, in their proper places within one shield, by impaling or quartering; and the joining of ensigns of honour and dominion with the paternal arms of the bearer, &c.

When a man marries he impales his wife's paternal arms, by placing them upright on the left side of his own in the same escutcheon, such impalement being also called *arms en baron et femme*. If that wife should be or become an heiress, the husband may bear her arms on an escutcheon of pretence over his own; Legh says, however, that this should not be done till he has begotten an heir of that heiress. In Scotland the husband frequently quarters the arms of his wife with his own when she is an heiress. In England this is only done by the children of such a marriage. If the mother be no heiress, the children cannot quarter her coat.

Another mode of impalement was by taking only half of each coat, and joining them in one escutcheon. This was called *dimidiation*; but the practice has long fallen into disuse.

The complete escutcheon of a family should never, according to some authorities, consist of more than six or eight quarterings; others admit of sixteen; and the Germans marshal sometimes twenty and thirty coats in one shield.

The best mode of marshalling so many is to begin by placing the arms of the first heiress who married into the family next to the paternal coat, and next to them the several coats which that heiress brought in; then the arms of the second heiress, followed by those which she brought in, and so on in rotation. When the royal arms are brought in by any match, it is usual however to give that match the second quarter next to the paternal coat, and some say it should even take precedence of that.

The arms of a widow are composed of her husband's and her father's impaled within a lozenge.

Those of a maid are her father's only, borne in a lozenge also, without any difference, except she be of the royal family, in which case a distinction is expressly furnished by the heralds for the individual coat by the command of the sovereign.

If the widow be an heiress, she may wear her paternal coat in an escutcheon of pretence over that of her husband, the latter however being in a lozenge, and her daughter, while unmarried, may quarter her mother's arms with her father's in a lozenge; but if the mother be no heiress, then, says Legh, the daughter has no further right to the arms of her mother's family, except to set them up pale-ways in her house to show her descent.

If the husband be a knight of the garter, or of any other order, the arms of the wife must not be impaled, but placed in a separate shield.

Such are the principal rules and terms of the science of heraldry: for further detail we must refer our readers to the works of Edmonson, Nisbett, Berry, &c., cautioning them, at the same time, against the Scylla and Charybdis of the heraldic inquirer, the absurd and misdirected enthusiasm of the champions of the art, and the undeserved contempt of its depreciators. By the latter it has been stigmatised as "the science of fools with long memories." It should rather be designated as a science which, properly directed, would make fools wise. It is, we repeat, a key to history which may yet unlock stores of information; at present its most learned professors have studied the art itself more than the use which may be made of it. They have wasted their time and their learning upon idle controversies, and still more idle speculations. A mysterious signification has been given to nearly every charge and tincture known in armoury, and a different one by nearly every writer upon the subject. The names of the ordinaries and colours have been derived from every sort of object and through every known language, without one fact having been elucidated on which we can depend. Even the word *blazon*, the only one we have ventured to hint the origin of, has been hotly claimed as Arabic by some disputants, and we will certainly not extend this article one line by an attempt to disprove it.

HERCULES, one of the old constellations, called *ἐγγόνασιν* by Aratus, Hyginus, and Ptolemy, and described by the first as "a figure like that of a man in sorrow" while the second offers various fabular significations from the stories of Hercules, Orpheus, Cetheus, Theseus, Thamyris, Ixion, Prometheus, &c. The club, lion's skin, and character of Hercules, are not so old as Aratus, who describes this figure as stretching his hands to different quarters, and makes an allusion to the neighbouring dragon, which shows that he was not painting a hero.

The constellation is situated between Draco, and Bootes, Lyra, and Ophiuchus; but as there is no star in it larger than of the third magnitude, there is nothing very remarkable about it. The stars α and β lie between the bright stars in the head of Ophiuchus and in Corona Borealis. The following is a list of the principal stars:—

Character.	No. in Catalogue of Flamsteed.	No. in Catalogue of British Association.	Magnitude.
γ	20	5466	3·5

HERCULES. [Heracles.]

HEREDITAMENT. [Chattels; Descent; Estate.]

HERESY, HERETICS. The word "heresy" (from *αἵρεσις, choice*) was originally used to express any opinion which a man adopted. Thus it was applied to the philosophic sects of Greece and Rome. (Cicero, 'Paradox. Proœm.') In the New Testament the term often simply denotes a religious party, without implying any censure. (Acts, v. 17; xv. 5; xxvi. 5; xxviii. 22.) Josephus calls the three great Jewish sects "*heresies*." ('Antiq. Jud.,' xiii., c. 5, s. 9.) But it is also used in the New Testament as a term of reproach. Thus it was applied by the Jews to Christianity (Acts, xxiv. 5, 14), and by the Apostles to those who resisted their doctrines (1 Cor., xi. 9; Gal., v. 20; 2 Pet. ii. 1; Tit., iii. 10). The fathers applied the words *heresy* and *heretics* respectively to opinions which were different from what they considered the doctrine of the Apostles, and to those who held such opinions, though some of the fathers draw a distinction between *heresy* as a wilful rejection of the doctrines of Scripture, and errors arising from ignorance or weak judgment. When the creed of the church began to be settled by ecclesiastical councils, all who refused to submit to their decisions were denounced as heretics. They were also called *heterodox*, while those who adhered to the opinions of the church were called *orthodox*, or *catholic*. Heretics were distinguished from unbelievers, inasmuch as they professed Christianity. Heresy must not be confounded with schism: the former relates to doctrine; the latter is any division on points of discipline. The number of heresies mentioned by early ecclesiastical writers is from 80 to 150; but Lardner ('Hist. of Heretics,' i. 5) has shown that many of these ought to be excluded from the list; nor have we any evidence that many of them had numerous followers.

Most of the heresies of the first two centuries related to the creation of the world, the origin of evil, the person of Christ, and the connection between Judaism and Christianity; and nearly all may be included under two great sects:—1. The Ebionites and Nazarenes, who, upon embracing Christianity, adhered to many Jewish opinions and ceremonies. 2. The Gnostics, who engrafted upon the Christian religion certain opinions of the Greek and Oriental philosophy. Some however regard the Ebionites as a sect of Gnostics. Both these heresies are supposed to have commenced in the Apostolic age, and to be referred to in the writings of St. Paul and St. John. [Ebionites; Gnostics.]

The Gnostics appear to have been very early divided among themselves concerning the respect which ought to be paid to the Mosaic law, and a new sect was formed by a Jewish Gnostic named Cerinthus [Cerinthus, in Biog. Div.] The Nicolaitans mentioned in the 'Apocalypse' (ii. 6, 15) are supposed to have been a sect of Gnostics, and some identify them with the Cerinthians. About A.D. 121, Valentinus, an Egyptian, engrafted some opinions of his own upon Gnosticism, and founded a new sect. His party was strongly opposed by Irenæus and Tertullian. Another sect which took its rise from the opinions of the Gnostics was that of Cerdo and the more celebrated Marcion, who began to propagate their tenets at Rome about A.D. 130. The principal feature of this heresy was the adoption of the Oriental belief in two supreme powers, the one good and the other evil. The principal followers of Marcion were Lucian, or Leucius, and Apelles. About A.D. 172, Bardesanes and Tatian gave rise to a new sect of Gnostics, which was chiefly distinguished by the practice of an austere discipline. These people were called, from their habits of abstinence, Encratites, Hydroparastates, and Apotactites. The Docetæ were a sect of Gnostics who sprung up very early. They held that the body of Christ was immaterial, and therefore did not suffer on the cross, but only appeared to die. Several minor sects of Gnostics are mentioned by ancient writers, such as the Adamites, the Cainites, the Sethians, and the Ophians, an account of which is given in Lardner's 'History of Heretics.' Lardner doubts the existence of such sects as the Adamites and Cainites. The sect of Eclectics, or New Platonists, was founded at Alexandria in the 2nd century; but though its tenets were embraced by many Christians, it is rather to be regarded as a philosophical than a Christian sect. [Eclectics.]

We now come to the heresies which existed from a very early age respecting the divinity of Christ. This doctrine was denied by some of the Ebionites in the 2nd century. [Ebionites.] About the end of that century Praxeas founded a new sect. Denying the doctrine of the Trinity, he held that the divine nature was intimately united with the person of Christ, whom he considered to be a mere man, but born of a virgin. His followers were called Monarchists, from their rejecting the doctrine of the Trinity; and Patripassians, because they were supposed to believe that the Father suffered on the cross: this opinion however they seem to have disclaimed. In the opinions of Praxeas ecclesiastical historians trace the germ of the Sabellian heresy. His chief antagonist was Tertullian. His opinions were held, with some slight variations, by his contemporaries Artemon and Theodotus. Among the heresies of this age respecting the creation of the world was that of Hermogenes, who believed in the eternity of matter.

The Montanists, who arose in Phrygia about the year 170 (some say 150), are rather to be looked upon as fanatics than heretics. Their leader Montanus claimed the character of a prophet: he appears to have differed from the orthodox in no leading doctrine, but only in some points of discipline. His opinions owe their celebrity chiefly perhaps to the circumstance that they were embraced by Tertullian. [Tertullian, in Biog. Div.] We find traces of this heresy down to the time of Augustine and Jerome. Some inconsiderable heresie arose in the 2nd century on points connected with the rites and ceremonies of the church, such as the Artotyrites and others, [Communion.]

In the 3rd century Gnosticism still had adherents, though it was fast falling into disrepute. But a new heresy arose out of the Oriental philosophy, headed by Manes, who attempted to unite the doctrines of the Persian Magi with those of the Apostles. [Manichæans.] The controversy on the Trinity and the person of Christ continued with increasing warmth. About the middle of the century the doctrines of Praxeas were revived, with slight variations, by Noëtus of Smyrna, Sabellius, an African bishop, and Beryllus, an Arabian. The last two were opposed by Dionysius of Alexandria and Origen. [Sabellius, in Biog. Div.] Another heresy relating to the same subject was established by Paul of Samosata, bishop of Antioch. A new sect of Ebionites, or Jewish Christians, appeared about the middle of the 3rd century, but it lasted only for a short time. They were called Elcesaites, from their founder Elxai. The Novatians, followers of Novatian, a presbyter of Rome, are reckoned, perhaps erroneously, among the heretics of this century. They held no doctrines different from those of the Catholic church, but maintained a greater severity of discipline; and hence they were called Puritans (*καθαροί*). By some historians they are regarded as austere and turbulent fanatics, while others rank them as the earliest sect of reformers in church discipline.

In the 4th century the attention of the church was chiefly occupied with the Arian controversy. [Arius, in Biog. Div.] Out of these disputes other heresies arose respecting the person of Christ, such as that of Apollinaris [Apollinaris, in Biog. Div.], Marcellus, Photinus, and Macedonius. Near the end of this century we find a new sect of Gnostics in Spain, under the name of Priscillianists. The Donatists, who caused great commotions in the church during this century, are rather to be classed as schismatics than with heretics. [Donatus, in Biog. Div.] For an account of certain minor sects in the 4th century, see Epiphanius, 'De Hæresiis.'

At the beginning of the 5th century the Pelagian controversy arose. [Pelagius, in Biog. Div.] The disputes concerning the Trinity and the person of Christ continued to give rise to new sects, the chief of which were the Nestorians and their opponents the Eutychians, or Monophysites. [Eutyches, in Biog. Div.] The controversies of these sects with the orthodox and each other continued nearly 200 years, producing various minor sects, such as the Monothelites, the

Anthropomorphites (who maintained, from Genesis, i. 27, that God had a human shape), and others.

The rapid spread of the monastic system in this century was warmly resisted by Vigilantius, who thus incurred the enmity of Jerome, and has been ranked among the heretics.

In the 6th century the Monophysites continued to branch out into new sects, several of which arose on the question whether the body of Christ was corruptible or incorruptible. Other minor sects are mentioned by Mosheim. ('Ecc. Hist.' vol. ii.) After this time most of the ancient sects remained in existence in different parts of the Christian world with greater or less vigour. The only new sect which requires a distinct notice is that of the Paulicians, which was formed in Armenia and Cappadocia in the 7th century. After suffering severe persecutions they were dispersed over Europe, in various parts of which they formed settlements about the 11th century. The origin of the Albigenses is traced to a body of Paulicians which settled in France. [ALBIGENSES.] The doctrines of the Paulicians have been identified by some with those of the Manichæans, while others regard them as reformers of the corruptions of the church. (Vaughan's 'Life of Wycliffe,' Introd., c. ii.)

Before the Reformation in England heresy was the holding of opinions contrary to the Catholic faith and the determination of Holy Church (2 Hen. IV. c. 15). The court in which a man could be convicted of heresy at common law, was that of the archbishop in a provincial synod. After conviction the criminal was delivered up to the king to do what he pleased with him. If the criminal had abjured his heresy and then relapsed, the king in council, upon a second conviction, might issue the writ De Hæretico comburendo, upon which the criminal was burnt alive. One Sawtre, it is said, was the first man burnt alive for heresy in England, and the writ De Hæretico comburendo was formed in this case. But the above-mentioned statute empowered the diocesan alone, without a synod, to commit a man for heretical opinions, and to imprison him as long as he chose, or fine him; or if he refused to abjure, or after abjuration relapsed, the sheriff, mayor, or other officer, who should be present, if required, with the ordinary or his commissary, when the sentence was pronounced, was to take the convict and burn him openly, without waiting for the king's writ.

It is unnecessary to mention the statutes of Henry VIII. relating to heresy. The Reformation was not fully established till the reign of Elizabeth, the first statute of whose reign repeals all the former enactments, and leaves heresy as it stood at common law. (5 Rep. 23). There is no statute that determines what heresy is. The statute of Elizabeth limited it to 'such as heretofore hath been adjudged heresy' by the authority of the Scripture or the first four councils. After the Reformation was fully established, heresy was punished by ecclesiastical censures, and by burning alive a criminal who had been convicted in a provincial synod. The writ for burning the heretic could not be demanded as a matter of right, being left to the discretion of the crown; but both Elizabeth and James I., in their discretion, thought proper to grant the writ. Elizabeth, it is said, burnt alive two anabaptists, and James two Arians.

The statute 29 Charles II. c. 9, abolished the writ De Hæretico comburendo; and heresy is now left entirely to the ecclesiastical courts. As Elizabeth and James practically showed their approbation of burning heretics alive, so Lord Coke (3 'Instit.' c. 5) approves of the punishment.

At present the ecclesiastical courts punish for heresy, when they do punish, *pro salute animae*, as it is termed—that is, solely out of regard to the soul of the offender. But it is difficult to say at present what can be called heresy; and perhaps it is difficult to say what is exactly the punishment for it.

Its history in England is instructive, but the change from burning alive to the free expression of opinion on religious matters is one of the greatest steps in the social progress of this country. For some other matters connected with the subject, see BLASPHEMY. (Blackst. 'Comm.' Mr. Kerr's ed., vol. iv. p. 40.)

HERIOT is a feudal service consisting in a chattel rendered to the lord on the death of a tenant, and in some places upon alienation of a tenant. It is stated to have originated in a voluntary gift made by the dying tenant to his lord and chieftain of his horse and armour. (Glanvile.) This render became first usual, then compulsory; and at an early period we find the ancient military gift sinking into the render of the best animal (at the election of the lord) possessed by the tenant, and sometimes a dead chattel, or a commutation in money. (Bracton, Fleta; Coke-Littleton.)

Heriots are either heriots-custom or heriots-service. Where a heriot is due from the dying tenant by reason of his filling the *character* or *relation of tenant* within a particular seigniory, honour, manor, or other district, in which it has been usual from time immemorial to make such renders upon death or alienation, it is called *heriot-custom*: *heriot-service* is a heriot due in respect of the *estate* of the tenant in the particular land held by him.

For heriot-custom the lord cannot distrain, because the duty arises out of the character or relation of tenant sustained by the party within the seigniory, &c., in which the custom is found to exist, and not, as in the case of heriot-service, in respect of the particular land holden. As the selection of the best animal is however with the lord, he may determine his choice by an actual seizure, upon which the property in the animal will vest in the lord by the mere act of seizing it.

But for heriot-service the lord may either seize or distrain. He may seize, because by this act of selection the property is vested in him; or he may distrain, because, the land being the debtor, the lord may, by the coercion of a distress upon that land, compel the succeeding tenant to deliver or procure the delivery of the heriot.

Where the heriot-service has been created since the time of legal memory, it is called a *heriot by reservation*, and sometimes a *suit-heriot*: if its origin go back beyond the limits of legal memory, it is called a *heriot by tenure*.

Heriot-custom formerly prevailed very extensively in freehold lands, but is now more commonly found in lands of customary tenure, whether copyholds,—the conventionary estates in Cornwall, held under the duke of Cornwall,—the customary estates called *customary freeholds* in the northern border counties,—or lands in ancient demesne.

Heriot-service may be reserved in respect of a freehold, or leasehold, or a customary tenure; but as, since the statutes of Quia Emptores and Prerogativâ Regis, it is probable that no new sub-tenures in fee have been created, and as it has not been usual to reserve heriots upon gifts in tail, or upon the creation of freehold leases for lives, heriot-service in modern times is generally found in connection with long leasehold estates, where, in consequence of some restriction imposed upon the exercise of the leasing power, or in token of respect for ancient usages, this species of render has been retained.

Heriots, whether heriots-service or heriots-custom, are multiplied whenever the land subject thereto becomes divided amongst different tenants holding distinct parts of such lands in severalty. Where therefore land is held subject to a heriot-service to be rendered at the death of a tenant, if the tenant alien part of the land a distinct heriot will be due upon the death of both the alienor and the alienee; and if such distinct heriots have in fact become due and have been rendered or compounded for during the alienation (whereby the lord will have obtained actual seisin of the several heriots), the liability to pay such multiplied heriots will continue, even though all the land should afterwards be reunited, and vest again in the same person. Inattention to these rules has caused some strange and contradictory decisions in the courts of Westminster. (2 Nevile and Mann, 798.)

A distress for heriot-service must be taken upon the land in respect of the tenure or upon the demise of which it is reserved; and where double or treble heriot has become payable by reason of alienation, the liability attaches severally upon each of the severed portions of the estate. All goods found upon the land, except such as are privileged from distress [DISTRESS], may be taken as a distress for a heriot-service, whether they belong to the tenant or to a stranger, such goods being held merely as a pledge for the performance of the service. But where a heriot-service is by the terms of the reservation commuted for a money payment (or rather, where the reservation of a contingent money payment is improperly designated a heriot), the reservation will be in substance a rent; and therefore the distress taken for this reservation (so miscalled a heriot), if not redeemed by payment, or replevied within five days after notice, may be sold as a distress for rent under the provisions of 2 William and Mary, c. 5.

Heriots were known in England before the complete development of the feudal system which followed upon the Norman conquest. The Normans introduced reliefs [RELIEF] without abolishing the analogous heriot. The *heregeate* (heriot) is mentioned and fixed by the laws of Canute, 67, &c. The Dano-Saxon 'heregeat' is derived by Spelman, and after him by Wilkins, from *herge* (more properly *here*), army. It means literally, "war-treasure," a contribution given to the lord to enable him to carry on war. Originally it seems to have been a poetical expression for the horse and armour which as before mentioned were the chattels given in the earliest times by way of heriot. In Scotland, where the render upon the death of the tenant is a pecuniary payment, it is called "lord's money," "hergeld," or "herrezeld."

HERMÆ, terminal or pillar statues, placed in Greece and Rome at the meeting of streets and roads, in front of houses, temples, and other public places. They were termed Hermæ from the head being usually that of Hermes. The pillar on which the head was placed was mostly quadrangular, the whole being the height of a man. Several of these Hermæ are in the British Museum. [TERMINUS.]

HERMES, one of the twelve Olympian deities of the ancient Greeks, known to the Romans as *Mercurius*. According to Hesiod ('Theog.,' 942), he was the son of Zeus and Maia, the daughter of Atlas. The attributes of this deity are numerous and of opposite kinds; but it appears probable that he was originally considered to preside over flocks and herds. Hesiod says ('Theog.,' 441) that the shepherds address their prayers to him; for which reason the statues of Hermes are frequently represented with a ram by his side or on his shoulders. ('Pausan.,' ii. 3, 4; v. 27, 5; ix. 22, 2. See also 'Iliad,' xix. 490-1.) The phallic form, which distinguished the Hermæ at Athens ('Herod.,' ii. 51), also appears to indicate that this god was considered to increase the fruitfulness of the fields and cattle. Herodotus informs us (ii. 51) that the Athenians were taught by the Pelasgians this manner of representing the statues of Hermes; and that the reasons for this custom are explained in the Samothracian mysteries. Hermes was represented in a similar manner at Cyllene in Elis. ('Pausan.', vi. 26, 3.) This custom is also spoken of by Cicero ('De Nat. Deor.', iii. 22) and

Macrobius ('Saturn.', i. 19). According to some traditions, Hermes is said to have been born in Arcadia ('Pausan.', viii. 16, 1), and to have been the father of Pan; but according to another tradition, he was born at Tanagra in Bœotia. ('Pausan.', ix. 20, 3.) He was worshipped by the Thessalians above all other deities. ('Herod.', v. 7.)

In Homer the name of this deity is usually Hermeias. He is represented as the messenger of Zeus and the gods, and he conducts the souls of the departed to Hades. In later times he was regarded as the god of eloquence; but this no doubt arose from the association of skill of speech with the herald's office. As god of eloquence tongues of animals were offered to him. Hermes was the inventor of the alphabet; of numbers; of music, and of musical instruments, as the lyre and the syrinx; also of weights and measures, and various other things. He was the patron of merchants and of gain, and even of thieving—of all things in fact the exercise of which required prudence, cunning, and dexterity. And he was the protector of travellers, heralds, poets, musicians, and of those engaged in gymnastic exercises.

All the accounts from Homer downwards, unite in attributing to him extreme acuteness, and a propensity for thieving. One of his very earliest deeds, according to some writers within a few hours of his birth, was to steal the oxen of Apollo, from Pieiria, though others place it at a later date. His later adventures mostly turn on the exercise of his talent in speech, his cunning, or his dexterity evinced in his employment as the messenger of the gods. He also acted as charioteer and cupbearer to Zeus. He was active, full of bodily vigour, swift of foot, fertile in resources, cheerful, sensual.

The statues of Hermes, which were originally square blocks with a carved head upon them, were placed in the doorways of most private houses and temples at Athens. They were also erected where several roads met, to point out the way, and in the gymnasia, or public places of exercise. In early art, Hermes is usually represented with a chlamys, or cloak; a petasus, or travelling hat; talaria, or winged sandals; and a caduceus (κηρύκειον in Greek) or wand, with two serpents twined about it, in his hand. Originally the kerukion was an olive branch or staff—Hermes among his many benefits having taught mankind the mode of cultivating the olive. In later examples the chlamys is much reduced in size; the petasus is almost always, and the caduceus often, a pair of wings; and the god holds a purse in his hand, or is frequently represented with the right hand uplifted as the god of eloquence. In small works he is figured as psychopompos, conveying souls to Hades, &c. The representations of the deity in ancient works of art are very numerous, whether as single figures or as a portion of a group.

The original seat of the worship of this deity appears to have been Arcadia, whence it spread all over Greece. Temples dedicated to him were numerous, both in Greece and Rome. The festivals of Hermes were in Greece called *Hermaia*, (Ἕρμαια).

The Egyptian god *Thoth* was called Hermes by the Greeks. His attributes correspond in many respects with those of the Grecian deity. According to Plutarch ('Sympos.' Probl. 3), the Egyptian Hermes is said to have invented letters in Egypt. According to Diodorus Siculus, who appears to have confounded the attributes of the Egyptian and Grecian deity, he was the inventor of almost all the arts and sciences: a vast number of works are attributed to him.

HERMIT, more properly *Eremite*, from the Greek ἐρημίτης, signifying an inhabitant of a desert, is the name given to such religious persons as retired from society without becoming members of any monastic community. The distinction between hermits and monks, and the origin of both, are explained under the term MONACHISM. See also ANCHORET and ASCETIC.

HERNIA (from ἔρνος, *ernos*, a branch), signifies the protrusion of any organ from its natural position in the body; as hernia cerebri, hernia pulmonis, when the brain or lung protrudes through an aperture in the skull or the chest. But when used alone, this term means what is commonly called a rupture, that is, the protrusion of any portion of the intestinal canal from the cavity of the abdomen.

Herniæ sometimes form without any evident cause, the intestine being gradually protruded; but more frequently they result from some violent bodily exertion, as lifting heavy weights, excessive coughing or straining; or from sudden jarrings or shocks, as in jumping or falling; or from blows on the abdomen.

The general characters distinguishing a hernia are, a tumour, neither red nor hot, and often not painful, situated at some part of the abdomen, most frequently in or near the groin; largest when the patient stands up, and often disappearing entirely when he lies down; distended by coughing or other violent expiration, and liable to variation in size by exercise or rest, by abstinence or taking food; often producing disorders of the digestive canal, as flatulency, colic, &c. In the cases in which the hernia forms suddenly, as in consequence of a great exertion, the patient feels as if something had given way at the groin or other part of the abdomen, and on putting his hand there he feels a tumour which may vary in size from that of a nut to that of his fist, is elastic, hard, and tense, and soon after the accident becomes painful and tender. In the other class of herniæ, which may be called spontaneous, the tumour forms almost imperceptibly to the patient, and grows larger regularly but slowly; is attended with no pain, but merely a sense of weakness about the part; and decreases greatly or entirely disappears in the recumbent posture. If a hernia can be returned into the abdomen at pleasure, it is not by itself a dangerous disease; but if it become strangulated, that is, if the intestine is so constricted by the parts through which it has passed that its contents cannot pass through it, and its vessels are so much compressed that active inflammation is excited, it constitutes one of the most serious accidents to which the human body is liable. The symptoms indicating strangulation of the intestine are obstinate constipation of the bowels; pain and tenderness of the tumour, and spreading from it over the whole surface of the abdomen; extreme restlessness and languor; nausea and vomiting; a hard, small, and rapid pulse; thirst and coldness of the limbs. If the hernia be not reduced, these symptoms will regularly increase, till mortification of the intestine ensues, and (except in some most rare cases) death rapidly follows.

The above symptoms and other circumstances are common to all herniæ wherever situated, and are only modified slightly by the part of the abdominal contents protruded, the narrowness of the part through which it is forced, and the constitution of the patient. But there are some local circumstances peculiar to each, according to the part at which the intestine is protruded, which require to be noticed in connection with the mode of returning each into the abdomen and of retaining it there.

The most frequent kind of rupture is the Inguinal, and it is far more common in males than in females. It forms a tumour, occupying either the groin alone, or extending thence more or less obliquely downwards between the thighs. To reduce it the patient should be laid on his back with his loins lower than either his shoulders or his hips, and the knee of the side on which the hernia has formed should be raised and turned a little inwards. The operator grasping a convenient portion of the tumour with his right hand, should press it in the direction contrary to that in which it has protruded, and there retain it, while with his left finger and thumb placed at the narrowest part of the swelling he moves the intestine from side to side, alternately pressing and relaxing it, so as to empty some of its contents, and force it into the abdomen. If any portion be pressed through, a slight gurgling noise will be heard, and by continued efforts the whole will most probably follow.

An inguinal hernia may attain the size of an adult's head or more; but a Femoral hernia, which is the kind most common in females, is rarely more than two inches in diameter, and generally much less. It is usually of a rounded form, situated just below the groin, about two inches from the middle line of the body, and always feels hard and tense. The principal constriction is deep in the thigh, directly under the tumour, which tends to pass upwards over the groin. In reducing it the position of the patient should be the same as for inguinal hernia: if the tumour be large enough to grasp, it should be pressed directly backwards, as if to force it deeper into the thigh; but if it cannot be grasped, it should be pressed in the same direction, with the balls of the thumbs placed side by side upon it.

In Umbilical and Ventral herniæ, which come straight out from the front of the abdomen, the globular and pendant tumours which they form, and which often attain a considerable size, should be grasped with one hand, and pressed directly backwards towards the spine, while the opposite hand, as in inguinal herniæ, guides the successive portions through the aperture.

Whatever be the situation or condition of a hernia, it should be at once, if possible, reduced. The patient should go to bed, and, after lying a short time on his back, with his knees raised, the intestine will often of itself recede into the abdomen, especially if it have been frequently protruded; but if it do not, then the manual operation just described should be employed. The force used in it should never be so violent as to give much pain, and in old herniæ little or none should be caused; nor should the manipulation be continued for more than a quarter of an hour at a time, nor so long as to bruise the tumour or make it tender. If it fail, there are several auxiliary means that may be employed, of which a selection must be made according to the circumstances of each individual case. The warm bath should be first tried in all cases; the patient should be placed up to the neck in water at a temperature of from 94° to 100°, and remain there till he becomes quite faint. Any pain or irritation that previous attempts at reduction may have produced will be greatly relieved by these means, and the state brought on by the bath is peculiarly favourable for the return of a hernia, both by relaxing all the tissues surrounding it, and, when faintness occurs, by relieving the intestine from the pressure of the muscles, which often present the chief obstacle to its return, but which in that state become powerless. As soon therefore as the patient complains of faintness, or after he has been in the bath for ten minutes or a quarter of an hour, an attempt should be made to reduce the hernia by manipulating it as already directed under water. In strong and robust men, and especially in cases where the hernia has recently formed, bleeding to faintness, either before or while in the bath, should be employed, and the same opportunity taken to try to replace the intestine. The abstraction of blood will be useful, not only by the faintness which it produces being a favourable state for reducing the hernia, but by its relieving the inflammation which always arises when the intestine is strangulated, and by checking it in its fatal progress. If the warm bath and bleeding fail, the patient should be placed between warm blankets to recover from their depressing effects, and no more manual attempts should be made for some time. The next means employed should be the continued application of cold by ice or a rapidly evaporating lotion laid over the tumour, and kept there unless it produces much pain, till all the tissues are contracted and hard, for it is by their equable and powerful contraction on the intestine, and by the diminution of its volume, that reduction is sometimes thus effected even without manipulation. A hernia may be sometimes reduced by placing the patient under the influence of chloroform. Should this fail, and the symptoms of strangulation be increasing, the only means left before operation is the tobacco enema. Great caution is necessary in employing it; it should never be used except in otherwise healthy and tolerably strong persons, nor till the other means have failed. A dram of tobacco being steeped in a pint of boiling water for ten minutes, half the infusion thus made should be used first; and if it produce no evidently depressing effect, the other half may be injected in half an hour afterwards. The usual consequence is an extreme degree of languor and sinking, a kind of deadly coldness and paleness, and the last stage of depression: in this state a last attempt at reduction should be made; and if still unsuccessful, an operation must be resorted to. The tobacco enema should not be employed unless the symptoms of strangulation be quite evident. If the hernia seem merely irreducible, but is not strangulated, and if cold, and warm bath and bleeding (if deemed advisable), have failed, the patient should be left, and an active dose of aperient medicine given him, for sometimes the bowels will, under the operation of these means, return of themselves into the abdomen.

When the hernia has been completely reduced, its recurrence must be prevented by the wearing of a truss. A truss consists of a circular pad, having one side convex and soft, and the other flattened and made very firm by a plate of steel, by which the pad is riveted into the spring, which is a narrow band of highly tempered and very elastic steel, forming when extended somewhat more than a semicircle. In applying a truss, the soft convex surface of the pad should be placed accurately over the part where the neck of the tumour was situated, that is, over the ring through which the intestine first protruded, and which may be felt by the weakness of the abdominal walls, so that the finger may be easily pushed almost into the abdomen, carrying the skin and subjacent tissues before it. The pad being held there, the spring should be made to pass round the haunch to the back, so as to reach just beyond the spine; its elasticity, tending to bring its two extremities together, will thus act so as to press with a certain force upon the ring or the canal through which the hernia was protruded, and thus supply the defect of weakness at that part of the abdominal walls. At that extremity of the spring which is applied near the spine there is affixed, in what are called common trusses, a leathern band, which is to be passed round the opposite haunch, and buckled or buttoned on the pad, so as to prevent its shifting its position during exercise; and in some cases, where this is apt to occur, another band should pass from behind under and inside the thigh and be fixed to the pad. Another very useful form of truss is that commonly called Salmon and Ody's or the self-adjusting truss, which has a second pad, to be placed behind on the spine, and which requires no bands to keep it fixed, but, by the steady pressure of its two pads towards each other, maintains a firm pressure on the ring, and permits the spring to move up and down upon the haunch during exertion. In applying this, one pad must be placed on the ring, the spring must pass round the opposite haunch, and the hinder pad must rest on the spine, just below the loins, where it is least moveable. When there is a hernia on each side, a double truss, that is, one with a pad for each side, and one or two springs long enough to reach quite round the body, must be worn: if there be two springs, they should be connected by a cross-band and buckle, so that they may be tightened or loosened behind, and another band should pass from one pad to the other to maintain them in their proper position. To determine the necessary length for the spring of the truss, a measure may be taken by a string fixed at one end over the centre of the ring, at that part where, when the patient coughs, the intestine may be felt endeavouring to protrude, and thence carried round in an oblique direction between the most prominent part of the hip and the top of the haunch-bone to an inch beyond the spine. The pad should be of a size proportioned to that of the ring, and the spring should be strong enough to make firm but not painful pressure.

HERO, HEROIC, HEROISM. These words flow directly from the original Greek word *Ἥρως*, which denoted (at least in the times subsequent to the Homeric poems) a person intermediate between gods and men, and usually of divine descent on at least one side. Such were worshipped with divine honours by those cities and races of men which claimed them as their founders or ancestors. This divine origin however was not essential: thus Philippus of Crotona, who fell in battle against the Phœnicians and Egestæans, was made a hero for his beauty; a heroon, or shrine, was built on the spot where he was buried, and sacrifices were offered to him. ('Herod.,' v. 47.) At a later age Aratus and Brasidas were worshipped as heroes at Sicyon and Amphipolis; and the Athenians slain at Marathon received similar honours. Concerning these last, legends were current which show that a supernatural and mythological character was really ascribed to them, and they probably were the latest of the Greeks to whom such a character was attributed. The Heroic age, properly so called, appears however to have terminated with the immediate descendants of the Greeks who returned from Troy, and to have extended backwards for an uncertain length, estimated by Mr. Thirlwall at six generations, or about 200 years. This is the fourth or Heroic age of Hesiod, in which Zeus "made the divine brood of heroes, better and braver than the third or brazen race" ('Days and Weeks,' 157), the princes and warriors of mythological history, such as Theseus, Perseus, and those who fought in the sieges of Thebes and of Troy. In Homer the word hero occurs frequently, but in quite a different sense: it is applied collectively to the whole body of fighters, Argeii, Danai and Achæi, without reference to individuals of peculiar merit; and indeed often appears to be used for little more than an expletive, when *he*, or *the man*, or *the soldier*, would have done equally well. Indeed the application of the word is not even limited to warriors; but is applied to heralds, wise counsellors, kings, &c. It has been suggested, with considerable plausibility, that the word originally denoted the members of those roving bands who in the earliest times overran Greece, issuing forth from the south of Thessaly and giving extension to the name, first of Achæans, and afterwards of Hellenes, as we learn from the legends in Pausanias and Thucydides; so that in the same sense the Normans who colonised Italy, or the Saxons who settled in England, might justly be called heroes. The root of the word seems to be *her*, whence the Latin and German forms of herus and herr (master), here, hertha, heracles, vir, virtus, &c. The same root seems to exist in the word Arimann, which denoted a particular order of freemen among the Lombards, existing at the time of the establishment of their empire after the Lombard conquests. There seems little doubt that this class originated in the warrior caste of the Lombard invaders, and the establishment of the name thus furnishes an analogy to the theory suggested above as to the origin of the Homeric use of the word hero. Even the name of German, and the meaning of brother attached to the word in Latin, may originate in the same sense of a member of an armed family or body: the root in all cases appearing to involve the notion of might or mastery. The Sanscrit word *sūra* appears to contain the same element as "heros."

The promiscuous (or Homeric) use of the word hero disappeared in the age succeeding the Homeric poems. It seems probable that the Hellenic invasion, commonly called the Return of the Heraclidæ, put an end to it. The new conquerors of Southern Greece do not seem themselves to have borne or used the title; and afterwards, when they, or their descendants, looked back to the warlike legends of the earlier race who had borne the title, the lays, exploits, and persons were called heroic; and from the combined effect of poetical exaggeration, reverence for antiquity, and traditions of national descent, the more modern Greek use of the word arose, carrying with it notions of mythical dignity, and of superiority to the later races of mankind. The custom of showing respect or affection by making precious offerings, and celebrating costly sacrifices at the tombs of the dead; the imaginative temper of the Greeks, which, as it loved to ascribe a divine genealogy to the great, was equally willing to admit them to a share of the divine nature and enjoyments after death; and the love of magnifying past ages, common to all nations, will sufficiently explain the change of earthly leaders into protecting genii or dæmons, who were believed immortal, invisible, though frequenting the earth, powerful to bestow good or evil, and therefore to be appeased or propitiated, like the gods themselves. In the age of Hesiod, as is evident from the passage above referred to, the age of heroes was past, and they were already invested with their mythological character, which appears to furnish one, among other reasons, for believing him to have lived after the Homeric age.

In the common English use of the words a hero denotes only the chief or most distinguished person, the hero of a victory, or the hero of a novel. Hudibras is the hero of Butler's poem; but hero and heroism still preserve their original characteristics, and are applied to actions evincing an unusual or even superhuman degree of bravery and virtue.

(Thirlwall's *History of Greece*, ch. v.; *Philolog. Mus.* No. 4, 'On the Homeric use of the word *Ἥρως*;' Wachsmuth's *Hell. Alt.*; Von Savigny's *History of the Roman Law during the Middle Ages*, vol. i., ch. 4.)

HERO'DIANS (Ἡρωδιανοί, Matt. xxii. 16; Mark iii. 6; xii. 13; see also Mark viii. 15), were in all probability a political party in Judæa, who were anxious to preserve the government in the hands of Herod's family. By some the Herodians are thought to have been a religious sect; but they are not mentioned either by Philo, or by Josephus in his enumeration of the Jewish sects. In their religious opinions they probably belonged to the sect of the Sadducees, since that which is called by Mark (viii. 15) "the leaven of Herod" is styled by Matthew (xvi. 6) "the leaven of the Sadducees." They were no doubt the partisans and followers of Herod the Great. This view is supported by the Syriac version of the New Testament, which renders Herodians, by servants of Herod. Politically, they advocated compliance with the idolatries and customs of the Romans, to which the Pharisees were opposed; and this opposition throws light upon the snare laid for Christ in the question propounded by both sects (Matt. xxii. 16, 17) as to the lawfulness of paying tribute to Cæsar. As the answer seems rather in favour of the Herodians, the leaven of Herod must have consisted of the idolatry.

HEROIC AGE. [HERO.]

HEROIC VERSE, in its ancient sense, means that which was the vehicle of Greek, and subsequently of Latin, epic poetry, of which the actions of the heroes were the appropriate subject. [HEXAMETER.] In

English, our common ten-syllable couplet passes under this name, chiefly, it should seem, because it is the measure into which the epics of antiquity have been most frequently translated. The Alexandrine of twelve syllables, however, has been also used by our elder writers for this purpose, as by Chapman in his translation of the 'Iliad.'

HERPES. The word herpes was employed in a very vague sense, and applied to many eruptions of different kinds, until restricted by Willan to a well-defined affection of the skin, characterised by the eruption of clusters of transparent globular vesicles, situated on a red and inflamed base extending some lines beyond them. The vesicles of each cluster commonly vary in size from a millet-seed to a very small pea; the clusters themselves are distinct, being separated by portions of perfectly healthy skin, and they generally rise in quick succession.

The eruption is preceded and accompanied by a degree of constitutional disturbance which generally varies with the extent of the local affection, being often slight and attracting no notice, when this is limited and consists of a few clusters only, but very great and marked by a high degree of fever, when the clusters are numerous and spread over an extensive surface in a young and plethoric subject.

The local affection is announced by a sensation of heat and tingling experienced in the part, and first appears as a small bright red spot, having in its centre a few very minute vesicles. These vesicles, which contain a transparent colourless fluid, rapidly enlarge, and, in the course of some hours, attain the size and present the form and aspect of very small pearls: in the thickest part of the cluster two or three of the vesicles coalesce, forming one of irregular figure and larger size. There is a sensation of pricking and smarting pain experienced in the part. The vesicles gradually become opaque, in the course of a few days shrivel, and are succeeded by brownish scabs: the heat and irritation of the portion of skin on which they are situated subside; and the scabs fall off, leaving a tender and reddened state of the skin, which soon disappears. The duration of the individual clusters, from their first appearance to the falling off of the scabs, varies from one to two weeks. When there is a succession of clusters, they all follow the same march; the febrile state persists as long as fresh vesicles continue to arise, and the affection may be prolonged to three or four weeks. In some cases the fluid is absorbed, the vesicles shrivel, and, at the end of four or five days the affection terminates in desquamation; in others, the fluid in the vesicles becomes purulent, and they are succeeded, especially when seated on the back, by superficial ulcerations, which prolong considerably the duration of the disease.

The clusters of vesicles, though they retain in all cases the same characters, and follow nearly the same march, are sometimes confined to a particular locality, justifying the designation, *H. labialis*, *H. præputialis*, or assume a particular arrangement, giving rise to the varieties, *Herpes zoster*, when they are situated on one half of the body and extend in a line or band; *H. phlyctenodes*, when they are disseminated; and *H. circinnatus*, when they occur in circles or rings.

In *H. labialis* the clusters are disposed irregularly about the mouth, generally on the external surface of the lips, in some cases extending to the cheeks and alæ nasi, and in rare instances occurring also in the pharynx. It occasionally comes on after irregularities in diet, or unusual exposure to cold winds, or to the atmosphere, as in travelling; at the termination of the hot stage, in ague; and during the course of catarrhal fevers and pneumonia. It is always a slight affection in itself, requiring no treatment beyond that of the disorder which it accompanies.

Herpes præputialis. In this variety there are one or more small clusters of vesicles, either on the external or internal surface of the prepuce. When situated externally, they follow the ordinary march or terminate in desquamation, and require no treatment, with the exception of the application of lint soaked in the lotion of acetate of lead, for the purpose of alleviating the itching and preventing the rupture of the vesicles and the consequent formation of an ulcer. When they occur on the internal surface of the prepuce, the vesicles are kept continually moist, break at the end of four or five days, and often give rise to an excoriation or superficial ulceration, which by an inattentive observer may be mistaken for a syphilitic sore. It soon heals under the influence of cleanliness, the local application of the lead lotion, and the administration of a few alteratives.

In *Herpes zoster*, Shingles, there is a succession of clusters of white silvery vesicles, forming an oblique line or band, limited to one-half of the body, and almost always occurring on the trunk. It is generally ushered in by severe febrile symptoms, and by smarting or deeply-seated pains, which indicate the future course of the eruption. Each cluster follows the march we have described, and the febrile state continues as long as there is a succession of vesicles. It is unattended with danger, excepting in old persons, where the clusters are occasionally followed by gangrenous and sloughy sores. In young and plethoric subjects the treatment should consist of bleeding, saline purgatives, diet, and the application to the part of a sedative lotion. This treatment alleviates the sufferings of the patient, but has very little influence on the march of the vesicles.

Herpes phlyctenodes differs from the preceding variety in the arrangement of the clusters, which are disseminated, and have no particular seat. When occurring extensively, the vesicles do not attain the size common to more limited forms of the eruption. It is often met with in children during dentition.

In *Herpes circinnatus*, or herpetic ringworm, the eruption is limited in extent, frequently of a circular form, and consists of extremely minute vesicles, which dry up and terminate in exfoliation, leaving a scurfy areola. It occurs frequently on the cheeks in children, and in women of delicate complexion, and is often confounded with a disease entirely different in its nature, contagious, and also, in popular language, denominated ringworm. This form of Herpes soon disappears under the influence of the local application of almost any astringent solution.

None of the varieties of Herpes are contagious, and all occur most frequently in the young, during spring and autumn, and in warm climates.

The existence of distinct groups of vesicles on red and inflamed bases is sufficient to distinguish Herpes from every other cutaneous affection.

HERRING FISHERY. [FISHERIES.]

HERTHA, the Goddess of Earth among the ancient Germans. As Hertha, she was the wife of Thor; but Roman writers sometimes speak of the deity as *Herthus*, a male god, and the companion of Thor. Tacitus ('Mor. German.,' c. 40), who calls Hertha the mother of the gods, says that she was worshipped by the Suevi, and that her sanctuary was in a grove in an island of the ocean, and was served by a single priest. A chariot, covered by a cloth to conceal the goddess, was taken out of the sanctuary on certain occasions, and was drawn by cows about the country with great solemnity. This was a time of general rejoicing, especially for those places which were honoured by the visit of the goddess. During that time a cessation of war took place, arms were laid aside, and peace reigned over the land, until the priest thought proper to restore the goddess to her sanctuary, where the chariot and the clothing, and the goddess herself, or her image, it was said, were washed in a secret pond, and the attendants who assisted at these ablutions were immediately after swallowed up by the flood. The report of these mysterious circumstances served to inspire the ignorant people with a dread of the power of the goddess, whom no mortal could behold with impunity. (Grimm, 'Deutsche Mythologie.')

HESPE'RIDES, in Greek mythology, a family of Nymphs, of the same parentage, and apparently the same with the Atlantides, though there are differences between them, especially in number (the Atlantides being usually reckoned seven, and the Hesperides three in number), which we must leave to be accounted for by the general uncertainty of mythological story. They were named Ægle, Arethusa, and Hesperethusa, possessed the faculty of melodious song, and were the daughters of Atlas, by Hesperis, the daughter of Hesperus. Some traditions, however, add a fourth sister, Hestia; and Hesiod makes the Hesperides the daughters of Night. They dwelt in a beautiful garden in the western parts of the earth, in which grew the celebrated tree which bore golden apples, the gift of Ge to Hera on her marriage with Zeus. These apples were guarded by a fierce dragon named Ladon, which never slept. Heracles killed the dragon and carried off the precious fruit. Some authors make the treasure to consist of sheep instead of apples, both being called by the same Greek word, *mela*. Some think them citrons or oranges. The Gardens of the Hesperides are variously placed, in an oasis of the African desert, in Cyrenaica, at the foot of Mount Atlas, and in the Happy Islands of the Atlantic.

HESPERIDIN. A neutral vegetable principle obtained from the spongy part of the peel of oranges and lemons, by digesting it in boiling water, and saturating the infusion with cream of lime, then evaporating to dryness, treating the residue with alcohol, and evaporating the filtered solution. The matter left is to be treated with twenty times its weight of distilled vinegar, and the solution set by for a week, when the hesperidin is deposited, and is to be purified by recrystallisations from alcohol.

The properties of hesperidin are: It forms white silky needles, grouped in tufts or in mammilated forms; they are inodorous, insipid, fuse at a gentle heat into a resinous substance which becomes electrical by friction; at a higher temperature, this substance decomposes without yielding ammonia, and burns with flame and an aromatic odour. It is insoluble in cold water, and requires sixty parts of boiling water for solution; it is very soluble in boiling alcohol, but insoluble in ether. Nitric acid renders hesperidin yellow; sulphuric acid gives it first a yellow and then a red tint; hydrochloric acid imparts a greenish yellow colour to it. The acetic solution of hesperidin is not decomposed by water; persulphate of iron precipitates it brownish-red; it is soluble in the alkalies. No analysis has as yet been made of hesperidin.

HESSENES. [ESSENES.]

HESTIA. [VESTA.]

HETEROGENEOUS. [HOMOGENEOUS.]

HETEROSCII (other-shadowed), an old astronomical term for persons living in such parts of the earth that their shadows at noon are always turned contrary ways. Thus the only heteroscii are those who are situated without the tropics, and in different hemispheres; since in the northern hemisphere those who are situated north of their tropic have the shadow at noon always turned northward, and those south of the southern tropic, southward.

HEVEENE (CnHn). An oily hydrocarbon found amongst the products of the destructive distillation of caoutchouc.

HEXACHLORXYLON ($C_{20}H_6Cl_6O$ or $C_{10}H_4Cl_4O_4$). A yellow crystalline derivative from creasote, obtained by the action of hydrochloric acid.

HEXACHORD (ἑξ, *six*, and χορδή, a *gut*, a *string*), a name given by the ancient Greeks to a lyre of six strings; also a scale of six sounds. In what is denominated 'the System of Guido," musical sounds are divided into three scales, named *Hexachords*. The first, from C to A, is called the *Natural* hexachord: the second, from G to E, the *Durum*; and the third, from F to D (the B flattened), the *Molle*. To the notes of each scale are assigned, as names, the syllables *ut*, *re*, *mi*, *fa*, *sol*, *la*. This perplexing and irrational system, which has been well designated *Crux tenellorum ingeniorum*, is now utterly discarded.

HEXAGON, a figure of six sides. [Regular Figures.]

HEXAHEDRON, a solid of six faces. [Cube; Regular Solids.]

HEXA'METER (ἑξ, six, *μέτρον*, measure) is the most important form of dactylic verse. [Dactylics.] It consists of six feet, either dactyls or spondees, with no limit in their arrangements, except that the fifth is usually a dactyl, and the sixth invariably a spondee. Great part of the beauty of a long poem written in this measure depends on the varied cadences, which may be produced by varying the cæsura. [Cæsura.] The most usual places are the middle of the third and the middle of the fourth foot: of these, the former is called by prosodians the *penthemimeral*; the latter, the *hephthemimeral cæsura*; as, for example:—

> Vix e conspectu | Siculæ telluris in altum.
> Non aliter quem qui adverso | vix flumine lembum.

That which is called the *bucolic* cæsura, at the end of the fourth foot hardly seems to deserve special mention, being in no respect essential to the harmony of the verse, and invariably accompanied by one of the two before mentioned. These are essential; and one or other of them is always observed in well-constructed verse, except in rare cases where the omission is intentional, with a view to some special effect. For the niceties of the measure, see the treatise of Hermann, 'De Metris,' lib ii. 32.

HEXAPLA, the plural of ἑξαπλοῦς, which means "six-fold," was an edition of the Scriptures of the Old Testament prepared by Origen, which exhibited, in addition to the original Hebrew text, six Greek versions in as many parallel columns; namely, the Septuagint, that of Aquila, that of Symmachus, that of Theodotion, one found at Jericho, and one found at Nicopolis in Epirus. It also comprehended a seventh version of the Psalms. The Hebrew text was besides given both in Hebrew and in Greek characters; so that, properly speaking, there were eight columns in all, whence the work is sometimes called Origen's Octapla. [Bible; Septuagint; and Origenes and Theodotion, in Biog. Div.]

HEXYL. [Caproic Alcohol, *Hexyl.*]

HEXYLENE ($C_{12}H_{12}$), *Oleene*, *Caproïlene*. The olefene of caproic alcohol. It is obtained by distilling hydroleic acid, and is also probably formed by the destructive distillation of many other fatty bodies. It is a colourless very mobile liquid, lighter than water, and possessing an arsenical odour. It is scarcely soluble in water, but easily so in alcohol and ether. Hexylene boils at 131° Fahr., and its vapour appears to exercise a deleterious influence upon animals. Birds which have inhaled it for some time fall dead.

HIERO'S FOUNTAIN, a philosophical toy illustrating some hydrodynamic details. It consists of three vessels connected by two tubes. Water descending from the top vessel, drives the air from the bottom into the middle vessel and compresses it, so that by its elasticity it forces the water in this vessel up a jet. It is only another form of *compressed air-fountain*.

HIEROGLYPHICS, a compound Greek word, meaning "sacred engravings," generally applied to the representations of animal and other forms sculptured on the monuments of Egypt, by means of which the Egyptians expressed their language. The ancient Greek authors call this mode of writing *hieroglyphic*, or *hierographic*, and attribute its invention to Thoth, the Egyptian Hermes. According to these authorities, it was the most ancient mode of writing known to mankind. It was called by the Egyptians *Neter tu*, or "sacred words," and was particularly used in all inscriptions relating to the gods, temples, and public events. Above 1000 different symbols appear on examination of the monuments to have been employed, and future observations will probably still further augment their number. These are arranged with great precision on the monuments, generally in horizontal or vertical lines, with all the animals and symbols of the same inscription facing in the same direction, whether to the right or to the left; sometimes, however, they are placed in the area, or field, and dispersed amongst the figures or scenes they are intended to illustrate. They have been divided into six classes: 1, sculptured and not painted; 2, those which are sculptured and painted; 3, *linear*, or drawn in outline; 4, drawn in outline and painted; 5, *polychrome*, or those painted with many colours; 6, *monochrome*, or those painted in one colour. Those carved on stone are generally executed in a peculiar kind of sculpture, called *cavo rilievo*, in raised relief below the surface, but sometimes in bas relief. The linear hieroglyphics are drawn with a carbonaceous black or a vermilion red ink, on papyri, linen, slices of stone, wood, and other materials. Hieroglyphics appear in use on the walls of the earliest tombs, and even scrawled on the blocks of stone of the great Pyramid built by Cheops, and they continued to be employed till the time of Caracalla, during a space of almost 3000 years; but subsequently were superseded by a more cursive writing called the Demotic; and finally, on the triumph of Christianity, by the modern Coptic. Some scattered notices of their general nature and the meaning of a few symbols are given by Diodorus, Chæremon, Clement of Alexandria, and Porphyry; and a special dissertation upon them, written by Horus Apollo, or Horapollo, of Phenebethis, A.D. 500, has been handed down; but a knowledge of them was little cultivated by the Greeks and Romans, even those who lived in Egypt itself. From the 10th century to the 16th century, all knowledge of them totally disappeared; and on the revival of learning, the task of decipherment and interpretation was vainly attempted, till the discovery of the Rosetta stone in 1799 gave a clue to their interpretation. This monument, found on the site of a temple dedicated by King Necho to the god Atum, which is a trigrammatical inscription in hieroglyphics, Demotic or cursive writing, and *Greek*, recites the decrees of a synod of priests assembled at Memphis, A.D. 196, in honour of Ptolemy V., their benefactor, and declares that the decree is ordered to be engraved in these three writings. After some feeble, although not unsuccessful, attempts to decipher the demotic by De Sacy and Akerblad in 1802, Young, in 1814, was the first to discover from the name of Ptolemy on this stone, and that of Berenice on a doorway in the south quarter of Karnak, that certain hieroglyphics were employed to represent sounds, not ideas, as had been hitherto conjectured. The removal by Bankes of a small obelisk from Philæ, erected by the priests in honour of Ptolemy Euergetes II. and Cleopatra, on the pedestal of which they had inscribed a Greek inscription, enabled Champollion in 1822 to compare the names of Cleopatra and Ptolemy, and, correcting some of the errors of Young, to extend the alphabet, and lay the foundation for the future decipherment and interpretation of the hieroglyphics. It was seen, from a comparison of these names and the recurrence of the same hieroglyphics in the same places, as if they were used as sounds, that this was their true employment; and by an extension of the decipherment, the names and titles of the Ptolemies, Roman emperors, and native monarchs, were readily discovered.

Since the time of Champollion, who published a Grammar in 1836, and Dictionary of Hieroglyphics in 1841, the study of the hieroglyphics has been pursued by Rosellini, Salrolini, Leemans, Lepsius, Brugsch, De Rougè, Birch, Goodwin, Hincks, and others.

The general results of these inquiries have shown that all hieroglyphical inscriptions, from the most remote to the latest periods, consist of two classes of characters, the first called by the Egyptologists *ideographs*, or symbols representing ideas, not sounds; and *phonetics*, or hieroglyphics employed as syllables, or letters of the alphabet. The great body of the inscriptions are composed of phonetics, at least to the extent of four-fifths of each entire text; and they are easily distinguished by their constant recurrence. They are, however, fewer in number than the *ideographs*.

These ideographs are divided into two classes: 1. The *ideographs* proper, or those which represent only one idea; as a seated man having the head of an ibis, to mean the god Thoth or Hermes; a wolf to represent that animal; and a bundle of flax to represent flax: these are direct imitations. 2. Those of the kind called by Clement *tropic*, or enigmatic, or metonymes, express the idea by less direct means, as a smoking pail, to signify milk; a pelican seizing a fish, to signify fishing; an ape, to express anger, on account of the irritability of the animal; and a jackal, cunning, on account of its crafty nature; an ostrich-feather, to signify truth, because all the feathers of the wing of that bird were supposed to be of equal length. These ideographs are often preceded by a group of *phonetics*, which spell the sound of the word, the sense of which they are intended to convey: thus, the wolf is preceded by a hare, A, a line of water, N, and a basin, SH, spelling *Ansh*, "wolf;" and the jackal by the back of a chair, S, and chisel, B, spelling *sab*, "crafty." These direct ideographs are the oldest part of the system, the remains of the primitive picture writing of the nation: about 700 have been found.

The *determinatives* form a sudivision of the ideographs, and are those symbols employed to represent more than one idea. They are extensively employed and repeated in the inscriptions. Some of these determinatives are employed in twenty similar senses, others convey two or three similar ideas. Their use is to abridge the too copious employment of ideographs, and to render clear the ambiguity of phonetic groups. Thus, the *sun's disk*, represented as a circle with a dot in the centre, signified all ideas connected with that luminary, as the sun, year, month, hour, day, night, light, darkness, orbit, festival; an *uræus* signified any goddess in the Pantheon, a seal-ring, to shut or to enclose. These determinatives, like the ideographs, are preceded by groups of phonetics, spelling the sound of the ideas they convey—thus, the sun's disc has before it phonetics reading *aten*, when it means a disc, and *tar* when it means "time." They *determine* in fact the genus of the idea of the phonetic group, and are often used instead, or in place of their corresponding ideographs, which are pictures so elaborate of the idea as to be unsuited for general purposes, and only fit for the most magnificently executed public monuments. Sometimes two determinatives, or an ideograph and determinative, are used after a phonetic group.

These determinatives in fact resemble the 214 keys or radicles of the Chinese, which are used in nearly the same manner. Similar determinatives were employed, although on a more limited scale, in the Assyrian and Babylonian cuneiform inscriptions, and were not abandoned in cuneiform systems till the time of the Persians, B. C. 525, only yielding way to the invention of the alphabet by the Phœnicians. About 170 hieroglyphic determinatives have been recognised. The discovery of this portion of the hieroglyphical system is due to Champollion, and he interpreted the sense of these two classes of ideographs by comparing the symbols with their explanation, when it remained, in ancient classical authors, by a careful analysis of the Rosetta inscription, by a due regard to their position in sentences, and by the analysis of the phonetic groups which preceded them. The discovery of the phonetic system, in fact, aided to discover the meaning of the ideographs and determinatives, and these in their turn shed light on the meaning of the phonetic groups. The 170 determinatives embrace the whole circle of ideas, and are used in the hieratic or cursive writing without ideographs, and accompanied only by their proper phonetic groups.

The hieroglyphics used to represent sounds, called *phonetics*, are fewer in number than the preceding, forming, however, a complete syllabarium of the spoken language. These syllables fall into two classes. Those ending with vowels, 52 in number, represent 18 sounds of the spoken language, and answer the purposes of a pure alphabet. They were sounded either according to the primitive pronunciation of the symbol chosen, or else according to the initial sound of the hieroglyph; thus a mouth, *ro*, represented the liquid R or L; and a hawk, *aakhom*, the vowel A; an owl, *mouladj*, its initial sound M. At the earlier period of the formation of the language some of these phonetics are preceded and followed by one already in common use, having the same sound: thus, a flying goose has before it a blind or window-mat P, and after it the eagle A, and placed in the centre of the group it is demonstrated or explained to have the syllabic value of PA. Each of these 54 letters, in fact, have, at the option of the scribe, the final hieroglyphic vowel which completed their syllable written after them, but by degrees this fell into desuetude, and they finally became almost purely alphabetic. To these must be added 57 hieroglyphs used for syllables terminating in consonants. These, like the preceding, have such hieroglyphs of the alphabetic series as represent their initial or final signs indifferently written before or after them, or omitted. For example, a star is used for the syllable SEB or SEV, sometimes with the back of a chair, the alphabetic S written before, in, and often with the leg, the alphabetic B or V after it. In some rare instances both the alphabetic hieroglyphs S and B are written before and after it, enclosing as it were the star in the midst. The whole of these hieroglyphic syllables are monosyllabic, and were sounded according to the primitive name of the object. These *phonetics* continued in general use till the age of the 22nd dynasty, or about B.C. 1000, when several ideographs were added by the priests, for alphabetic and syllabic sounds, and this innovation, which went on increasing till A.D. 200, when the number amounted to about 90 additional characters, gives a complex alphabet and syllabarium of nearly 200 hieroglyphics in common use.

The phonetics formed the great body of the language, all the grammatical forms, and abstract prefixes and affixes, substantive and auxiliary verbs, being composed of them only. Groups of phonetics precede or replace the ideographs and determinatives, and give the sounds of the ideas intended. They are constantly interchanged among themselves, and these equations of sound are called *variants*. In the long interval of nearly 3000 years, the many papyri containing similar texts give hundreds of words written with different symbols.

It is now necessary to say something of the nature of the language as shown by the phonetics. The words are principally Coptic, but this language has lost so much of its vocabulary that it is inadequate to explain half the hieroglyphical words, which amount to about 4000. The verbal root in hieroglyphics is unchangeable, the nouns and adjectives being declined by prefixes, as *bak*, a hawk, *pa bak* the hawk, *en bak*, of a hawk, *er bak*, to a hawk; the plural has *iu* added as *bak-iu*, hawks. The verb is conjugated by affixes, as *maa* to see, *maa a* I see, *maa na*, I saw, and auxiliaries, as *au a her maa*, I was seeing or saw. The pronouns are very numerous. The prepositions are often vague, and appear in their original composite form, which they have lost in most other languages, thus, *her hat* "over the heart," is "in the midst," *em-khen* "in the hall" is "within." The syntax is exceedingly regular, the verb appearing first, then the objective, and finally the instrumental case. Some verbs are transitive, others neuter, and the genders of nouns are indicated by affixes and prefixes. The distinction between active and passive is but slight.

With respect to style, the monumental, except where colloquies are introduced, is elliptic and laconic, and the hieratic style of the Ritual and religious works partakes of the same characters. Even verse or rhythm has been found; the expressions are flowery with oriental imagery, antithesis and metaphor. The lapidary hieroglyphical inscriptions are almost all religious, historical, or sepulchral. With the exception of the Ritual, [PAPYRI] the books of the Egyptians were written in a cursive or writing hand, of a very distinct clear shape, like our ancient court or law hand, in horizontal lines with headings at the top of the page, and rubrics. This *hieratic* character, as it is called, employed far fewer symbols than the hieroglyphic, and approached nearer to the alphabetic system, but still made a copious use of determinatives. It has been traced up as early as the 6th dynasty, and continued till the 2nd or 3rd century, A.D. It was also employed for official documents, correspondence, memoranda, and drafts, as the only written language till the commencement of the 26th dynasty, about 800 B.C., when a second written language was introduced, called the *epistolary*, *demotic*, or *demodic*, that is, popular, or *enchorial*, that is, native. After the 8th century B.C., the hieratic was only used for religious purposes, chiefly copies of the Ritual. At its commencement, the *demotic* was only an abridgment of the hieratic, but it rapidly lost all resemblance with hieratic forms, abandoned to a great extent, although not entirely, the use of ideographic and determinative signs, and endeavoured to accommodate the written language as nearly as possible to the alphabetical Phœnician and Greek systems then known to the Egyptians. It continued in use till the 3rd century, when it was finally superseded by the Coptic; the triumph of Christianity in Egypt having done away with the last form in which the vain superstitions of paganism remained enshrined in the writings of the Valentinians, Gnostics, and other heretics. The demotic was extensively used under the Ptolemies and Romans for letters, and other documents, and was first learnt by youth, who, after they had mastered it, according to Clement, proceeded to learn the hieratic and hieroglyphic, then an old and dead writing, the knowledge of which was only to be acquired by a special study. The demotic, although it may appear paradoxical, is the most difficult of the Egyptian cursive hands to decypher, while the documents written in it have less attraction to the student from the dry nature of their contents.

Besides the Egyptians, the ancient Æthiopians also carved hieroglyphics on their pyramids and public monuments. These resemble those used during the later days of the Egyptian monarchy, and expressed the sounds of the Amharic or Æthiopic dialects: they have not yet been interpreted. The elder Democritus, B.C. 459, wrote, it appears, a dissertation on Æthiopian hieroglyphs. At Nineveh, Koyunjik, and even in the isles of the Greek Archipelago, objects have been found with hieroglyphical inscriptions, not in the Egyptian language, perhaps unmeaning imitations, like the obelisks erected by some of the Roman emperors.

The term hieroglyphics has also been applied to the writings and paintings of the ancient Mexicans, by which they depicted the various occurrences of life. The Mexican system was more pictorial than the Egyptian, the subjects were actually painted, but certain symbols or hieroglyphs were introduced to aid their explanations. The symbol expressive of the king's name is attached by a cord over the head of the figure of the monarch, that of the name of persons, of towns, and hills, is expressed in the same manner. After the introduction of Christianity some of the symbols were employed phonetically. This symbolical system of pictorial writing prevailed in Central America and Yucatan before their conquest by the Spaniards.

The term hieroglyphics was also used by writers in the 16th century to certain emblemata which they invented and illustrated, and by astrologers and almanac makers to the symbolical pictures, by which they pretended to show the events likely to happen in the course of the year.

(For the principal works on hieroglyphics, the reader is referred to Young, *Account of Discoveries in Hieroglyphical Literature*, 8vo. Lond. 1820; Champollion, *Précis du Systéme Hièroglyphique*, 8vo., Paris, 1824; *Grammaire Égyptienne*, fo., Paris, 1836; Lepsius, *Lettre à M. Rosellini*, 8vo., Rome, 1837; Brugsch, *Scriptura demotica*, 4to., Berlin, 1848; Birch, *Introduction to the Study of the Hieroglyphs*, 12mo., London, 1857.)

HIGH COMMISSION COURT, a tribunal established by Queen Elizabeth under the authority of a clause in the Supremacy Act (1 Eliz. c. 3), which exercised arbitrary power in matters of faith and in ecclesiastical concerns, as the Star Chamber did in civil affairs. The commissioners were forty-four in number, of whom twelve were ecclesiastics, and three commissioners constituted a quorum. Their jurisdiction extended over the whole of the kingdom, and was not confined to the clergy, but included all classes. They were directed to visit, reform, redress, order, correct, and amend all errors, heresies, schisms, abuses, offences, contempts, and enormities whatsoever, which by any ecclesiastical authority whatever might be lawfully ordered or corrected. The commissioners, or any three of them, judged at their own discretion of any speech or writing which tended to heresy or schism. All appeals from the inferior ecclesiastical courts were carried before the Court of High Commission. The court was empowered to punish incests, adulteries, fornications, and to inquire into matters relating to matrimonial offences. Other ecclesiastical courts had been subject since the Reformation to inhibitions from the supreme courts of law, but this court was exempt. It exercised its powers therefore without control, and was authorised to conduct its proceedings, not only by the ordinary legal processes, by juries and witnesses, but to use "all other means and ways which they could devise." This empowered them to resort to the rack, to torture, inquisition, and imprisonment, and to proceed, not upon information, but at their own discretion upon rumour and suspicion. The court could bring before it a suspected person, and by administering to him an oath, compel him to answer any question, and thereby criminate himself or his friends. Refusal to take this oath was punishable by imprisonment.

Fines were levied which often ruined the offender, and he might b imprisoned for any length of time at the discretion of the court. Th great object for which the court was established was more especially to punish any departure from the Act of Uniformity in matters of religion or in the services and ceremonies of the Established Church. Elizabeth, in a letter to the Archbishop of Canterbury, said she was resolved "that no man should be suffered to decline, either on the left hand or on the right hand, from the drawn line limited by authority and by her laws and injunctions." The Commons remonstrated feebly against the tyranny of the Court of High Commission, and by way of answer she granted towards the close of her reign a new patent in which the powers of the court were in some respects extended.

In the reign of James I. the sentences of the Court of High Commission were most generally confined to deprivation; but when the Commons remonstrated on account of its proceedings he refused to interfere. In 1610, by virtue of the royal prerogative, he established a Court of High Commission in Scotland, the authority of which was readily acknowledged by the bishops and some of the clergy.

In 1641, the Court of High Commission and the Star Chamber were both abolished, and a clause was introduced into the act which prohibited the revival of the former court or any other of a like nature. James II., however, issued a new commission, and appointed seven commissioners to exercise full and unlimited authority over the Church of England, and with the full powers of the former courts. Sancroft, archbishop of Canterbury, refused to be a member. Four of the commissioners were bishops, and the three laymen were the Earl of Rochester, Chancellor Jeffries, and Lord Chief Justice Herbert. The Revolution swept away this arbitrary institution.

HINDU ARCHITECTURE. [INDIA, ARCHITECTURE OF.]

HINDU CASTES. The division of the Hindus into classes or castes, with fixed occupations, existed from the earliest times: the word caste is derived from the Portuguese word *casta*, "race," or "lineage;" in Sanskrit they are called *varnas*, that is, "colours." The most ancient portion of the Vedas alludes to such a division; and in the laws of Manu, the Ramayana, the Mahabharata, and all the other Sanskrit works of the greatest antiquity, we find the system of castes fully developed. The Greeks who visited the country describe its inhabitants as distributed into certain classes. (Arrian, 'Indic.,' c. 11, 12; Diodor. Sic., ii., c. 40, 41; Strabo, xv., c. 1, pp. 485-6, Casaubon; Pliny, 'Hist. Nat.,' vi., c. 19.) We have no means of ascertaining the origin of this institution. Heeren supposes that it was founded upon conquest; the first three tribes being a foreign race, who subdued the aborigines of the country and reduced them to an inferior caste: while others trace it "as the result of that fondness of perpetuating, like heir-looms, by descent from father to son, certain offices or the exercise of certain arts and professions, which is so peculiarly characteristic of almost all nations of the Indo-Germanic race."

All the Hindu writings recognise only four pure castes: Brahmans, Kshatriyas, Vaisyas, and Sudras. Pliny ('Nat. Hist.,' vi. 19) appears to have heard of the same number; but Megasthenes, from whom Arrian, Strabo, and Diodorus Siculus derive their account, mentions seven classes:—1, philosophers; 2, agriculturists; 3, herdsmen and hunters; 4, handicraftsmen and artizans; 5, warriors; 6, public inspectors; 7, royal councillors. But Megasthenes has evidently separated into distinct classes individuals belonging to the same class; the public inspectors and royal councillors belonged without doubt to the Brahmanical class, as well as the philosophers; the agriculturists, herdsmen, and hunters to the Vaisyas; and the handicraftsmen and artizans to the Sudras.

The following extract from the 'Jatimala,' a Sanskrit work on Hindu castes, gives the common Hindu tradition respecting the origin of each caste. "In the first creation by Brahma, Brahmanas proceeded, with the Veda, from the mouth of Brahma. From his arms Kshatriyas sprung; so from his thigh Vaisyas, from his foot Sudras, were produced: all with their females. The Lord of Creation viewing them, said, 'What shall be your occupations?' They replied, 'We are not our own masters; oh, God, command us what to undertake.' Viewing and comparing their labours, he made the first tribe superior over the rest. As the first had great inclination for the divine sciences (*Brahme veda*), therefore he was Brahmana. The protector from ill (*Kshayate*) was Kshatriya. Him whose profession (*Vesa*) consists in commerce, which promotes the success of wars for the protection of himself and mankind, and in husbandry and attendance on cattle, he called Vaisya. The other should voluntarily serve the three tribes, and therefore he became a Sudra; he should humble himself at their feet."

A strong line of demarcation is drawn between the first three castes and the Sudras. The former are allowed to receive instruction from the Vedas, and are considered to have been born again in a spiritual sense, whence they are called regenerate. The emblem of this second-birth is a peculiar kind of girdle or cord, which differs according to the caste; and with which a Brahman may be invested from his eighth to his sixteenth year, a Kshatriya from his eleventh to his twenty-second year, and a Vaisya from his twelfth to his twenty-fourth year; hough in certain cases the investiture may be made in the fifth, sixth, or eighth year respectively. ('Manu,' ii., 36-38.) A Sudra on the contrary is not reckoned among the regenerate; and would, according to the ancient Hindu law, be put to death for reading the Vedas.

The Brahmans possess the exclusive privilege of teaching the Vedas, and were in former times in the exclusive possession of all knowledge. Though the sovereign of the country was chosen from the Kshatriya class, the Brahmans possessed the real power, and were the royal councillors, the judges, and magistrates of the country. ('Manu,' viii. 1, 9, 11.) Their persons and property were inviolable; and though they committed the greatest crimes, they could only be banished from the kingdom. ('Manu,' viii. 380.) They were to be treated by sovereigns with the greatest respect; for "a Brahman, whether learned or ignorant, is a powerful divinity." ('Manu,' ix. 313-317.) The curse of a Brahman could consign even the gods to misery; and the Ramayana and Mahabharata contain numerous instances of the withering effects of such a curse.

The proper duty of a Brahman is to teach the Vedas, to perform sacrifices to the gods, and to meditate upon divine and holy objects. At an early age he is placed under the instruction of a Brahman, called a *Guru*, whose commands he is bound to obey, and whom he must reverence as a spiritual parent. When he arrives at years of maturity it becomes his duty to marry, and to lead a life of religious contemplation. He ought to be supported by the contributions of the rich, and not to be obliged to gain his subsistence by any laborious or useful occupation. But as all the Brahmans could not be maintained by the working classes of the community, it was found necessary to allow them to engage in other occupations; and it is accordingly provided in the laws of Manu, that a Brahman, unable to subsist by his religious duties, "may live by the duty of a soldier, and if unable to get a subsistence by this employment, may subsist as a mercantile man, applying himself to tillage and attendance on cattle." ('Manu,' x., 81, 82.) In seasons of distress a further latitude is given. The practice of medicine and other learned professions, painting and other arts, work for wages, menial service, alms and usury, are among the modes of subsistence allowed to Brahmans. (Colebrooke, 'On Indian Classes,' in 'As. Res.' vol. v.; 'Miscell. Essays,' vol. ii., pp. 186-7.)

The Brahmans still hold the first rank in Hindu society and are treated with great respect in all parts of Hindustan. But in consequence of the conquest of the country by foreign rulers, and the prevalence of many sects that have rejected their authority, they no longer possess the power they once enjoyed. The increasing acquaintance of the Hindus with the English language and literature, and the establishment of public schools, are tending still further to diminish their influence.

The Brahmans are separated into two great classes, one of which occupies the countries towards the north, and the other the countries towards the south. The southern Brahmans "hold in great contempt those from Kasi or Benares, as being men from the north; and would not even admit them to the honour of eating in their houses. The northern Brahmans are however at least as proud as those from the south, and allege several reasons for holding them in contempt; among which the most urgent is, that the women of the southern Brahmans are allowed to appear in public." (Buchanan's 'Journey from Madras through Mysore,' &c. In the Deccan the Brahmans are also divided into Vaidikas, who subsist by charity, and dedicate their lives to study and devotion; Lokikas, who follow worldly pursuits; and Numbis, who officiate in temples and perform menial duties to the idols.

The Kshatriya, or military class, is said by the Brahmans to be extinct. The decay of the Kshatriya class may have been owing to the peaceful habits of the people and their freedom from foreign invasion, and the consequent want of employment for a military class. But according to an ancient tradition the Kshatriya caste was destroyed by Parasu Rama, the sixth incarnation of Vishnu, and their land bestowed upon the Brahmans. The laws of Manu appear to refer to the same tradition in a passage where a list of Kshatriyas is given who, "by the omission of holy rites and by seeing no Brahmans, have gradually sunk among men to the lowest of the four classes." (x. 43, 44.)

The duty of the Sudra is servile attendance upon the higher classes, and especially the Brahmans, but he may also follow mechanical occupations, as joinery and masonry, and practical arts, as painting and writing; and although a man of a lower tribe is in general restricted from the arts of a higher class, the Sudra is expressly permitted to become a trader or a husbandman. (Colebrooke, 'On Indian Classes'—'Miscell. Essays,' vol. ii., p. 187.) The statements of Robertson, Mill, and many other writers, respecting the strictly hereditary nature of all trades and occupations in India, are considerably exaggerated. The liberty which is given to the Brahmans, even by the laws of Manu, has already been remarked; and a similar latitude is allowed to the Kshatriya and Vaisya classes. Mr. Colebrooke, whose opinion, from his extensive acquaintance with Hindu literature, and from his long residence in India, is entitled to the greatest respect, remarks, "that almost every occupation, though regularly it be the profession of a particular class, is open to most other tribes; and that the limitations, far from being rigorous, reserve only one peculiar profession, that of the Brahmana, which consists in teaching the Veda, and assisting at religious ceremonies." It is the opinion of some Europeans who have acquired an accurate knowledge of the manners and customs of the natives, that Europeans in general give too much credit to the assertions of the natives concerning the rules of their caste, which are commonly alleged as an excuse for declining any duty that is disagreeable.

A great portion of the population of India does not belong to any of the four pure castes. The individuals who form what is usually termed the impure or mixed classes, called in Sanskrit *Varna-Sankara*, that is, "mixture or confusion of classes," are either the original inhabitants of the country who have never professed the Hindu faith, or persons who originally belonged to one of the four pure classes, and have either lost caste themselves, or are descended from those who had lost caste, or the offspring of marriages between persons of different castes. The faults which occasion a lost of caste, and for which no pardon can be given, are—1, Sexual intercourse within the prohibited degree of consanguinity; 2, Sexual intercourse with any prohibited class; 3, Eating forbidden fruit, or drinking intoxicating liquors; 4, Stealing; 5, Slaying any animal of the cow kind, or of the human species; but a Brahmin is permitted to kill his enemy in battle; 6, Eating in company with persons of another caste, or of food dressed by their impure hands.—7, Eating on board a ship food that has been dressed there; 8, Omitting to perform the ceremonies due to deceased parents. But the greater number of impure or mixed classes has arisen from the intermarriage of persons of different classes.

Numerous other classes are formed from the intermarriage of the twelve mixed classes that have already been enumerated. One of the best known of the impure classes is that of the Pariahs, a corruption of the Tamul name *Parriar*, in the Deccan. They are called *Maliwanlu* in Telingana, and *Walliars* in Carnata. Their numbers are very considerable.

There are other tribes, which are considered inferior even to the Pariahs. Such are the *Pallis* and the *Pulias*, in the southern part of the Deccan; the *Curubarus*, the *Lambadis*, the *Dumbarus*, the *Chensu Carirs*, and many others.

HINGE, a kind of joint, usually made of iron or brass, upon which doors, gates, shutters, box-covers, &c., are made to turn in the act of opening and shutting. Hinges are constructed in a great variety of forms; but in most of the commoner kinds the action is that of a hollow cylinder working round a fixed central pin. In Collinge's patent hinges, which are peculiarly adapted for hanging large heavy doors and gates, the principal rubbing action is between a hollow cap and an accurately turned sphere, formed, as it were, upon the end of a pin: a cavity being provided for the reception of a supply of oil to lubricate the rubbing surfaces. Redmund's rising hinges, so frequently used for hanging room-doors in houses of superior character, have, like ordinary hinges, a hollow cylinder divided into two or more portions, attached one to the door and one or more to the door-post; but instead of the hollow cylinders being divided transversely *at right angles*, they are divided by spiral or rather helical lines. The result of this contrivance is, that when the door is opened it is lifted up a little from the floor by the sliding upon one another of the inclined helical surfaces; so that although the door may shut very close to the floor, it rises when opened, to a sufficient height above the floor to allow its lower edge to clear the carpet. Another advantage of this kind of hinge is, that the weight of the door acting upon the inclined rubbing surfaces of the hinges, causes it gently to close itself so soon as the hand is removed from it; but as this might in some cases prove inconvenient, a modification is introduced to allow the door to remain open at 90°, or more. In some cases a small spring is attached to hinges of this description, to aid the closing of the door when it has been opened but a little way. Hinges supplied with much more powerful springs are often used for the doors of public offices, where it is desired to render the closing of the door both certain and quick. For such doors hinges which will open in either direction and cause the door to spring back to its original position are often used. Whitechurch's ingenious hinge is an apparatus by which doors or windows may be opened at pleasure either on the right or left hand; or by which, in other words, either edge of the door may be made, at pleasure, the opening edge. A handle is fixed near each side of the door or window, by turning which the required positions of the apparatus are varied at pleasure: the action of this handle being to disconnect or release the door from the style or post near which it is placed, and at the same moment to complete its connection with the opposite style. This apparatus is, however, too complex for general use. Nettlefold's hinge, for the doors of book-cases, has a contrivance by which two adjacent doors opening in contrary directions may be hung without an intervening style: the two doors being connected together by a hinge resembling that by which ordinary doors are hung, and the axis of this hinge being connected with the edge of a thin partition in the book-case by metal brackets above and below the hinge, the space occupied by which is notched or cut out of the edges of the doors. Doors hung in this way fold completely back, and the hinges do not offer the slightest impediment to the removal of the volumes which happen to stand next to the partition, and which, were the doors hung in the usual way, could only be removed by first taking out those which stand adjacent to them. There are many other kinds of hinges of recent introduction, but not calling for special description.

HIPPARAFFIN ($C_{16}H_8NO_2$?), a white crystallisable substance obtained in small quantity by the action of peroxide of lead upon hippuric acid. It is inodorous and tasteless, very soluble in alcohol and ether, and fuses at 390° Fahr.

HIPPODROME (ἱππόδρομος), a large inclosed space appropriated by the ancient Greeks for their horse and chariot races. There appears to have been little substantial difference between the Greek hippodrome and the Roman circus, except that, from the Romans not having been accustomed to allow more than four chariots to compete at once, the circus was made much narrower than the hippodrome. Bearing this distinction in mind, and that the number of chariots which ran necessitated a more complicated arrangement of the *carceres*,—they being placed along a line formed like the prow of a ship with the apex towards the area, and each of the sides 400 feet long,—a sufficiently clear conception of the form and character of the hippodrome will be obtained by a reference to the article CIRCUS. The races will be found described under OLYMPIAN GAMES.

HIPPURATES. [HIPPURIC ACID.]

HIPPURIC ACID ($C_{18}H_8NO_5$, HO) is found in large quantities in the urine of the cow, the horse, and other herbivorous animals. It has also been detected in human urine. It is procured by evaporating the urine of the horse or cow to a small bulk, and acidulating with hydrochloric acid. The mixture deposits brown crystals of hippuric acid, which may be made white by boiling with lime, dissolving the hippurate of lime,[1] and again adding hydrochloric acid, when the pure hippuric acid is thrown down. It forms large semi-transparent four-sided prisms, which are sparingly soluble in cold water, and very soluble in hot water and in alcohol. Under heat it melts and gives off benzoic acid, benzoate of ammonia, and a fragrant oily substance. It forms salts which are soluble and crystallisable.

Concentrated boiling hydrochloric acid converts hippuric acid into benzoic acid and sugar of gelatin.

$$\underbrace{C_{18}H_9NO_6}_{\text{Hippuric acid.}} + 2HO = \underbrace{C_{14}H_6O_4}_{\text{Benzoic acid.}} + \underbrace{C_4H_5NO_4}_{\text{Sugar of gelatin.}}$$

When the salts of hippuric acid are fused with an excess of potash or lime they furnish ammonia and benzole, a reaction which is characteristic of this acid.

The salts of hippuric acid are termed *hippurates*.

HIRCIC ACID. This substance was obtained by Chevreul from the fat of the goat.

To prepare it, the aqueous product of the distillation of the liquid acid separated from the soap of goat's fat is saturated with baryta. After having evaporated the solution, the dry salt is decomposed by dilute sulphuric acid; the hircic acid then floats on the surface of the liquid in the form of an oil.

This acid remains fluid at 32°; it is lighter than water, smells of the goat, is insoluble in water, and forms soluble salts with potash and baryta. It has not been analysed.

HIRCIN, a principle similar to butyrin, which exists in goat's fat and in mutton suet, combined with olein. Its name is derived from *hircus*; and it is obtained from the fat of the goat by a process similar to that by which butyrin is procured, from which it appears to differ by yielding hircic acid, by treatment with the caustic alkalies.

HIRING OF SERVANTS. [SERVANTS.]

HISTORY. The notion that is contained in the word History appears to be often conceived both indistinctly and incompletely. If we trace the word to its original (ἱστορία), which simply means "inquiry" or "search" after facts, and includes the notion of recording them, we obtain a notion which, though distinct as far as it goes, will not enable us to distinguish history from annals [ANNALS]; and if we examine a series of works which bear the name of histories, we shall find many of them deficient in every characteristic which shall be sufficient to distinguish them from bare records of events arranged in chronological order.

In modern times a popular use of the word history has obtained, which may help us in arriving at a more precise notion of what is included in the term. Such expressions as a "History of the Steam-Engine," a "History of Printing," &c., are in common use, and are understood to signify a statement, arranged in chronological order, of the original discovery, and of the various steps and processes by which such discovery has been perfected, and the art, which is the subject-matter of the history, has been brought to its present state. Such a history, then, is nothing more than the explanation of the present condition or state of any given thing, by connecting it with an explanation of all the previous states of the same thing. But whatever propriety there may be in such an application of the word history, it is obvious that a bare narrative, however complete, of the successive mechanical contrivances by which the steam-engine or the printing-machine have advanced from their first rude beginnings to their present perfection, cannot fully satisfy the desire of knowledge when it is once called into action. If the description of such successive mechanical improvements were not connected with social progress, the scientific exhibition of such development, though it might interest the few, would not command the attention nor excite the sympathies of the many. And this leads at once to the conclusion that the various steps and processes by which every art and science has been brought to its present state, cannot be viewed simply by themselves, without relation to each other, and without relation to their effects on the happiness of mankind. All such special history, then, is viewed by us, though often unconsciously, as nothing more than an exhibition of the progress and perfecting of certain elements or ingredients which help to make up that entirety which is called society,—a word which expresses an aggregate of human beings and the infinite relations which unite them.

Another example of history in a limited sense, and one which brings us a step nearer to a proper conception of the subject, is the life of an individual. That branch of the historical art which treats of the life of an individual has long since obtained the specific name of biography. The reason why this species of composition has always given so much pleasure, and often conveyed so much instruction, is clear. To desire to know the past, to ascertain how that which now is became what it is, and the successive steps of its development, is an active principle in our intellectual and moral composition. It is this which stimulates the geologist to his minute investigations into the phenomena which present themselves on the surface of this globe. He labours, if not with the hope of finally attaining a complete view of the successive stages which have determined the actual state of things, yet with the reasonable certainty of learning something, and of being rewarded by a more exact and comprehensive view of the whole present condition of the earth. Such is the interest which some few individuals can create for themselves in branches of investigation which to mankind in general are distasteful or repulsive. But everything which concerns a human being excites the universal sympathies of mankind; and when we hear of those who have greatly dared or suffered, or those who by their talents and virtues have been the benefactors of mankind, or by their vices have inflicted misery on thousands of their own and succeeding generations, we desire to know all the minutest circumstances of the parentage, education, and life of such individuals. We desire to know how they finally became possessed of that character which distinguishes them from other men, and how they finally accomplished that for which their names are remembered. The history of an individual is so far like the history of a nation, that it involves a progress from a beginning to a certain definite point; and though the life of an individual cannot be viewed detached from that of his age and country, it possesses for all the purposes of instruction a sufficient analogy to the life of a nation. The commencement of the national life is generally hidden in the obscurity and the meanness of its origin; its termination, also, is not marked by any event so distinct as that of an individual death, but its condition at any one state, like that of an individual, is to be deduced only from a full comprehension of all the preceding circumstances of its existence.

We may then conclude that the history of any nation is a statement in chronological order of the various actions and events by which the society which constitutes that nation has attained and is in its actual state; meaning by its actual state (so far as such a term is capable of definition), its aggregate means of happiness. But though such a statement as we have just mentioned of actions and events, when they are judiciously arranged, will of itself indicate the general principles which from time to time have more or less affected the condition of society, the purpose of the historian is distinguished from the labour of the annalist by the philosophical character which he gives to his work. It is true that history, even thus viewed, may be written by one man more particularly with reference to one kind of actions and events, and by another man more particularly with reference to another kind; but as the subject of history is the progressive development of society, the historian who best seizes on those things which at each stage characterise this progress, will approach nearest to giving his work a real philosophical character. The religion, the positive morality, the legislation, the education, and the domestic habits of a people, are matters which intimately affect the happiness of a nation. Their progress in the mechanical or other arts is not to be overlooked, for their material prosperity largely influences their moral condition. While, then, the philosophic historian, in tracing the progress of any given society from its origin to its development, omits no event in his series that shall be necessary to link the present with the past, he more particularly directs his attention to the consideration of those civil and religious institutions, and to those popular notions of right and wrong, of virtue and vice, which lie at the bottom of every society that has existed or does exist, however disguised or obscured by the structure which has been reared upon them. To trace to their origin, and to view in their simplest forms, these elements of society,—to seize with precision and completeness their characteristics and their differences,—to follow them in the progress of their development and modification, both as influencing and being influenced by the new elements which from time to time enter into the composition of society, and so to show at each stage of its progress, not only the condition of society, but the causes which determine such condition,—such may be called a philosophic exhibition of history, or, in other words, a determination of the general principles which govern any given society, and the consequences which flow from them.

As this determination of general principles and of their effects forms the scientific part of the subject of history, so the mode of treating and exhibiting such a subject is the artistic part. No exact rules can be laid down for the treatment of history as a branch of art. It may be simply said that while the main object is to instruct, it is also an object to please, independent of the pleasure given by the mere communication of knowledge; that out of the infinite number of events which mark the progress of society, a few are often sufficient for the purpose of the historian, and that in the selection of the most appropriate he will show his judgment and skill; that while he clearly points out those great principles which have had most influence on the condition of society, he will not overload his work with reflections which the matter will suggest to the reader; and he will often not do more than put him in the way of following out a train of thought. His art will often teach him to conceal his purpose of instruction, when his work will not be prejudiced by his apparent forgetfulness of the dignity of his subject.

To enumerate among the historian's qualifications those of industry, integrity, and sound knowledge, or to detail all the qualifications for executing his task in the best possible manner, would be superfluous, if not impertinent. We will, instead of this, briefly consider the value of his labours when complete, and the advantage which his readers will derive from a careful perusal of his work and an examination of the original sources.

It is a common remark that all history is uncertain, and if the remark were true to the full extent, there would be little use in attempting to show the value of that which cannot be known with certainty. But though many events, or rather the circumstances of such events, are uncertain, the most valuable part of history rests upon monuments which have no uncertainty in their character. The positive institutions of every civilised country, its laws and its literature, are facts recorded, which are rich in instruction, independent of their being evidence of an infinite number of other facts of which they are conclusive proof.

The study of these monuments, whether prosecuted under the guidance of a historian who has used them in the construction of his work, or followed out by individuals according to their own judgment and mainly with reference to some special branch of inquiry, is one of the noblest subjects that can engage our attention. Such a study aims at the philosophical exposition of what now is, by reference to what has led to it: it shows what principles lie at the roots of our social system, what they once were, how they have been modified, and what they now are. Knowing what each thing now is, and how it came to be what it is, we are better enabled to form a conjecture of what it will be, and how we may best fashion it to our purposes. Thus, we learn in what circumstances change may be made with advantage; and knowing, from the experience which history teaches, that changes in our social relations become necessary in the course of time, and can neither be resisted with safety nor safely left to be directed by the blind impulse of numbers, we learn how to introduce such changes with the least chance of injury. But such a study, to be prosecuted with success, must be the occupation of a whole life: and if the active man of business into whose hands legislation and administration have been entrusted by choice, or fallen by perverse accident, has neither leisure nor capacity for so extensive a survey, he ought to learn enough to know his incapacity, and to ask counsel of those who are able to give it.

For him who would aspire to the high rank of a reformer of the institutions and the laws of his country, a sound and comprehensive knowledge of the leading notions contained in such institutions and laws, and of their progressive development, is absolutely essential to success in attempting any beneficial change. For in every case of change, the question is not merely, what would be best in the formation of a new society (if such a thing as the formation of a new society could for a moment be supposed), but the question is—what is best in the actual circumstances: and a full or a competent knowledge of actual circumstances must from the very nature of things comprehend a knowledge of previous circumstances.

To those whose business it is to interpret the laws of their country, whether in the way of giving advice or of judicial exposition, a full knowledge of fundamental principles, whether expressed in written laws or resting on recognised customs, is indispensable, in order to enable them to solve the numerous difficulties which attend the complete exposition of rights in a society which has existed for centuries continually progressive in wealth and in numbers. Such an active and living principle can alone maintain the study and the exposition of law in a state of healthy vigour in the midst of the complicated relations of modern society; and such alone can form a sound basis on which to construct a code, if ever the experiment should be found advisable.

What are the advantages of a complete historical study to the philosopher, who would operate upon the popular opinion and impress on his countrymen and the world those principles which he has discovered, or believes, to be the best principles of human action?

While the mass, who are intolerant of the labour of inquiry and reflection, or are deficient in the power of grasping general principles, cling to every existing thing, and every traditional opinion, with the instinct of self-preservation, those who possess, or think they possess (which is the more common case) enlarged philosophical principles, are apt to overlook the conditions which are necessary for their practical application. Thus each actually existing school of philosophy expects to accomplish everything in its own day: it despises the knowledge of the past, and would anticipate the enlarged experience of the future. But the effort to unsettle what has long existed fails before the inert resistance of accumulated ages, embodied in the habits, opinions, and institutions of the actual generation. The anticipation of universal change and complete reformation of social habits and opinions is indulged in for a few short years, sometimes mingled with contempt of those who pertinaciously look behind them, instead of embracing the offered means of perfectibility and throwing away all doubts as to the future. An instructive lesson is all that remains of these brilliant expectations. We learn the folly of wrestling with a power which we have not duly estimated, and of opposing to opinions and habits hardened by the growth of centuries, even the soundest conclusions of our philosophy, when unaided by the experience of history.

HOAR-FROST. The circumstances of terrestrial radiation, chiefly, but not exclusively, nocturnal, under which the aqueous vapour of the atmosphere becomes condensed upon the bodies in contact with it, have already been discussed and explained at some length in the article Dew. If the temperature of those bodies be reduced below the freezing point of water, hoar-frost is produced, the most characteristic form of which differs from dew only "by being frozen in the moment of deposition, and therefore accreting in crystalline spiculæ." But it occasionally happens, as also mentioned already, that after the globules of water constituting dew have been deposited, they are frozen, and become another form of hoar-frost.

In calm weather of the requisite low temperature, without fog, hoar-frost is seen in great perfection, especially in those mornings which are preceded by clear and cold nights, accompanied by a great deposition of moisture, or of what would have been moisture had not the freezing process interfered. It then imparts to trees and shrubs, and out-door objects in general, a great degree of beauty and richness of effect, fringing the leaves of plants with myriads of spiculæ, suspended either parallel to each other, or inclined at various angles, of all lengths, crossing and recrossing, and forming innumerable combinations. In some observations by Mr. Glaisher, first published in the 'Philosophical Transactions' for 1847, and subsequently in the Report of the Council of the British Meteorological Society for 1854, he describes the manner in which these spiculæ were formed on various plants. "The *leaves of the laurel*," he found, "were fringed with spikes one-tenth of an inch in length, and inclined to the leaf both upwards and downwards at an angle of 60°; but none were in the plane of the leaf continued. On the surface of the leaf were spikes down each fibre, one-sixteenth of an inch in length. The leaf itself, in the intermediate spaces, was covered with small white particles. The *leaves of the privet* were richly fringed with spikes for a quarter of an inch within the leaf; the spikes were about a quarter of an inch in length. . . . . *Broom* was most richly encrusted with spikes all round; by far the greater number, and longer than the rest, springing from the sides of each branch. There were comparatively few on the top, and none there were vertical. . . . *Grass* was very beautiful. The blade I found to be covered with white particles, which increased to spikes, becoming longer and larger the further from the root, terminating at the top in a rich circular cluster of spikes, set at all angles from 0° to 60°, and one-tenth of an inch in length. The spikes towards the end of the blade were nearly horizontal, or in the plane of the blade continued. The lower part towards the root was free and untouched by frost." From this latter circumstance, and that previously mentioned of the increase in magnitude of the spikes in proportion to their distance from the root, it may be inferred that the vegetable heat in that region of the plant counteracted the reduction of temperature by radiation, which had occasioned the deposition of hoar-frost on the blades.

Guided as he had been in his experimental researches on terrestrial radiation, and on the deposition of dew, by those previously instituted by Dr. Wells, Mr. Glaisher made a series of experiments also on the formation of hoar-frost on various substances exposed to the atmosphere under the requisite conditions.

Glass, raised one inch high above the ground, was covered with spikes one-sixteenth of an inch in length, and all arranged horizontally at the edges. Glass on grass was free from hoar-frost, doubtless on account of the greater radiating power of the latter, the atmosphere in contact with the glass remaining at a higher temperature.

On metals, such as copper, lead, zinc, tin, iron, &c., there were neither laminæ nor spikes of any kind; but *tin*, raised one inch high, was a little whitened at the edges.

Of three forms of carbon, all powerful radiators, on charcoal and graphite there were spikes in rich clusters, each group radiating from the same point, the spiculæ being generally inclined at all angles; and on lamp-black the spikes were very numerous, being about three-eighths of an inch in thickness, and inclined at an angle of about 30°, and at all azimuths, or in every direction with respect to the cardinal points; each cluster formed a circle, in the centre of which there were no spikes.

On sand there were spikes one-fourth of an inch in length. Chalk was covered with a mass of spikes of the same length. Whiting, which is chalk prepared by grinding, and suspension in water, and subsequent slight consolidation, was covered with rich bunches of spikes three-eighths of an inch in length.

Of cotton wool, every fibre was encrusted with a beautiful fringe of hoar-frost, and there were also a few spikes of ice. Upon flax there were no spikes, it being covered with white round particles (globules of dew frozen?) with small sparkling flakes of ice. Wood was covered with spikes a quarter of an inch in thickness, inclined to the horizon at an angle of 60°, and at all azimuths. Sawdust was very beautifully covered with spiculæ fans, formed by several spikes emanating from the same point at all angles greater than 30° with the horizon. These spikes were connected with each other by lateral spikes or bands, the whole forming the appearance of a fan, whose extent was 120°. Paper was covered with small round particles and a few spikes.

Raw wool was richly clustered on each fibre, so as to be about six times its own size; the spikes were three-fourths of an inch in length, and piled one upon another. Raw wool raised was similarly covered to flax, and displayed only a few spikes running in the direction of its fibres.

Raw silk was covered with spikes one-sixteenth of an inch in length, two of which emanated from the same point, at right angles to the fibre, and whose angle of separation was 30°.

The various modes of aggregation of the minute crystals of ice which constitute hoar-frost, are evidently dependent on differences in the texture, and in the radiating and conducting powers of these materials, and present a field for investigation hitherto little cultivated.

In England generally, as the observations of the late Professor Daniell, confirmed by the researches of Mr. Glaisher, have shown, vegetation is liable to be affected at night, from the influence of radiation, by a temperature below the freezing point of water, every month in the year, even in July and August. This explains the observed fact of the existence of hoar-frost in the early morning, in every season, even in the mildest climates of this country.

But in the Island of Guernsey, in the English Channel, where frost in general is neither frequent nor lasting, hoar-frost, according to Dr. Samuel Elliot Hoskins, F.R.S., is also of rare occurrence, owing partly to the high night temperature, and partly to the constant presence of a breeze, more or less fresh. Neither is hoar-frost general in the island when it does take place, being confined to elevated and bleak situations, and chiefly limited to the months of January and February. Spring vegetation here therefore is rarely checked by that condition which seriously interferes with early crops, even in the mild districts of Devonshire and Cornwall, where the husbandman is often driven to the necessity of protecting early vegetable productions by slight layers of straw, in order that they may not be chilled by their own radiation and the consequent deposition of hoar-frost upon them; or to the more troublesome operation of lighting fires to windward during cold clear nights, in order to produce a warm and virtually cloudy local atmosphere, and so to counteract the radiating process and its consequences.

Ice is also formed on the stems of plants and on certain inorganic bodies, by a process very different from that resulting in the production of hoar-frost, with which, however, it is popularly confounded. The facts respecting it will be stated in another article.

[Dew; Hail; Ice; Meteorology; Radiation of Heat; Snow.]

HOE, HORSE-HOEING. The hoe is an instrument used in gardens and in the fields for loosening the earth, and destroying the weeds between plants. It has various forms. The most common hoe consists of a blade or flat piece of iron, with an eye in which a handle is inserted at an acute angle with the plane of the blade. This hoe is used by striking the edge of it down into the ground, and the earth is moved by drawing the handle towards the workman. Another hoe has the handle at a very obtuse angle, and is used by pushing it forward and cutting off the weeds an inch or less under the surface of the ground. Hoes are made of different sizes and shapes according to the work which is to be done. When the earth is to be stirred between plants which are very near each other, the hoe is narrow and pointed, so that the smallest weed may be taken out close to the growing plant. When the distance is considerable, the hoe is wide, and sometimes compounded of several hoes, in order to stir a greater width of earth at once.

One of the greatest improvements in practical agriculture has been the introduction of the hoe into the field for every kind of crop. Peas and beans were probably the first crops which were sown in rows for the purpose of hoeing the intervals; potatoes, turnips, and carrots were probably the next, and the good effects produced on these crops, by stirring and hoeing the intervals between the plants, have led to the drilling of every other kind of produce which is apt to be injured by weeds. Hand-hoeing not having been found sufficiently expeditious on a large scale, a hoe has been invented of a larger form to be drawn by a horse. The rows have in consequence been widened, and this has introduced the horse-hoeing husbandry, which, half a century ago, was thought so important a discovery as to receive the name of the New Husbandry. The great promoter of this system was Jethro Tull, a gentleman from near Hungerford in Berkshire, who having observed the good effects of stirring the soil around plants, imagined that tillage might supersede all manuring, and that by keeping the soil free from weeds and continually stirred and pulverised, an inexhaustible fertility might be produced, and successive crops of the same kind might be raised without limit. The horse-hoe was the chief agent in this system, which imitated that of alternate crops and fallows; for the intervals between the rows in which the seed was sown were kept in a constant state of tillage, and thus fallowed for the reception of the seed for the next crop. Although these high expectations were not fulfilled, the hoeing of the intervals has caused a very great increase in the produce of the land, especially when united with judicious ploughing and manuring, and a proper succession of crops.

The simple horse-hoe is an instrument with a beam like a plough, and two stilts or handles, but much lighter; in this beam, and in branches from it are inserted, instead of coulters, the ends of iron hoes of the proper breadth to stir the whole surface between the rows. A small wheel is generally added to keep the hoe at a proper depth in the soil.

A horse draws the instrument, which is held and guided like a plough.

From this simple instrument a variety of others have been invented of a more complicated nature, but the object of them all is the same, namely, to stir the ground between the rows, and destroy the weeds as fast as they appear.

This horse-hoe is now chiefly used in the cultivation of peas, beans, potatoes, cabbages, turnips, and carrots.

The effect of hoeing is remarkable in very dry weather. Although the stirring of the soil would seem to extract what little moisture there might be in it, and the weeds wither on its surface, it soon appears that, on the contrary, moisture is attracted or produced, and the plants which drooped before appear refreshed and invigorated. This is probably effected by a chemical action of the air on the vegetable portion of the soil and on the roots of the plants, which have the power of combining the gaseous principles in various ways. Whatever be the mode in which it acts, experience has proved that the more the earth is stirred around plants the better they thrive.

When the intervals are very wide, as is the case where potatoes, turnips, or cabbages grow in rows, a light plough, with one horse, going up and down the intervals, answers the double purpose of a hoe and plough. It stirs the ground to a greater depth, and can be guided nearer to the growing plants than the common horse-hoe. It also turns the soil over into the middle of the interval, from which it may afterwards, when it has been improved by exposure to the air and rains, be thrown back towards the roots and stems of the plants.

The operation of hoeing cannot be performed too soon after the plant has shot out its roots, because the ground may then be stirred very near the young plant without danger, and the roots will spread readily in the newly-stirred soil.

In stiff soils it is often very difficult to use the horse-hoe, owing to the hardness of the surface, which rises in lumps, the very reverse of what is intended; but a little attention to the time of hoeing and to the weather will generally obviate this difficulty. If the soil is bound at the surface, it is a proof that the preceding tillage has not been so perfect as it ought; that the ground has not been stirred to a sufficient depth before winter, nor laid up sufficiently dry, or that it wants underdraining. There are few soils which may not be made mellow and crumbling some time or other in spring, and if the proper time be chosen for the first hoeing, the surface will scarcely ever become so compact as to rise in large clods. In the case of a very tenacious soil the small-spiked roller may be had recourse to, and after using it a few times in dry weather, the surface will be left in a fit state for the common horse-hoe. The method usually adopted in the horse-hoeing husbandry has been taken from the common cultivation of the maize or Indian corn in Lombardy. The rows there are about 27 to 30 inches distant: as soon as the plants are out of the ground, the earth is taken from the plants and laid in a ridge in the centre of the interval; here it is exposed to the sun and rains, which, besides killing the weeds, makes it much finer. In this state it is thrown back upon the plants and laid against the stems, which strike fresh roots into this mellow ground. But this will not be equally proper with all plants and in all soils. Both potatoes and cabbages are much improved by heaping up the loose soil over them; but this is not the case with many other plants. The beet, for example, while it is growing and swelling, is not benefited by having earth thrown round it, for this would induce the root to send out fibres sideways, whereas they should strike downwards in search of moisture. Turnips need not be covered with earth from the intervals, but they may after growth be protected from the frost by this covering. By attending to the growth of any plant we may soon discover when it is advantageous to move the earth from the roots and stems, and when it is best to draw it up around them. With respect to the destruction of weeds, there can be no doubt as to its great importance to all crops. It is generally supposed that every time that wheat is hoed judiciously, more than a bushel per acre is added to the crop, besides the benefit which the land receives by eradicating the weeds. Two or three good hand-hoeings will often so completely clear a field of weeds as to render superfluous the fallow which would otherwise have been necessary, and thus save all the expense of fallowing and the loss of one crop in four or five.

A great oversight is often committed when a field is hoed. The parts nearest to the fences and the sides of the banks, where the plough has not been able to go, are seldom hoed; but these parts become by neglect prolific nurseries of all kinds of weeds, which ripen their seeds, and disseminate them all over the field. No part of the surface should be left unhoed; and when the hoers leave a field, they should be able to defy any one to pick up a growing weed in it.

Those who employ labourers to hoe a field, at a certain price per acre, should be careful to see that the whole ground between the rows and the plants has been stirred; for it is a common trick to throw the earth over the growing weeds, and bury them only, without cutting them up, by which instead of being destroyed, they flourish more vigorously.

The best time for hoeing stiff soils is when they are neither wet nor dry; when the surface is slightly caked, but there is moisture below it, and when the weather is dry after some rain. Light soils can be hoed at any time, and require it oftener than the heavy, especially in showery weather.

A horse-hoe, in which a framework 8 or 10 feet wide supported on large wheels carries twelve to twenty hoes attached to coulters hanging at intervals of a few inches from one another, is used now in the cultivation of drilled corn crops during the earlier stages of their growth. Messrs. Garrett, of Saxmundham, Suffolk, invented an instrument of this kind, which has since been largely copied, in which the width cultivated and number of intervals hoed at once corresponds exactly with the width and rows which had been sown at once by the drill. It thus only needs that the hoe be placed on the exact rows which had been sown at one and the same time by the drill, and any crookedness or unevenness in the row will be followed by the hoes. That unevenness is of course common to all the rows of that width, and it only needs, in guiding the framework of hoes which, rigid together, hang in one piece, that one row be looked to and preserved, and all the others will be safe. Garrett's horse-hoe is now largely used in corn growing districts. One horse will thus cultivate 6 or 8 acres a day, at a cost of not more than 1*s.* an acre, where formerly 4*s.* an acre was expended in hand-hoeing.

HOG. The hog is one of the domestic animals which is most widely dispersed through the world, and yields to no other in its usefulness. It lives and thrives on every kind of food, vegetable or animal. It grazes like the ox, and will even eat hay; and its stomach can digest what few other animals could swallow with impunity. The sow may bear two litters in the year, having from eight to twelve, and even sometimes eighteen or twenty young at a time. No animal converts a given quantity of corn or other nutritive food so soon into fat, or can be made fat on so great a variety of food.

The food of the hog in a wild state is grass, roots, acorns, beech-mast, and wild fruits. He is active and ferocious; and the boar-hunt, from the danger which attends it, is well adapted to excite those who are of a warlike disposition.

There are many varieties of the domestic hog. The brindled hog most nearly resembles the wild species; but although the flesh is savoury, he does not fatten so soon, nor is he so profitable as the more indolent and softer skinned sorts are. The great quality of a hog is his power of digestion; the more rapidly he fattens, and the earlier he can be made to increase in flesh without increasing in bone, the better is the breed. Some of the small hogs which are brought from China are remarkable for this quality, as well as for their prolific nature; and when, by judicious crossing, the size is increased, they are a very profitable breed. The Chinese pig is short in the head, with ears pricked up and pointing backwards, very wide in the cheek, high in the chine, and short in the leg. When a sow of this breed is heavy in pig, her belly generally drags on the ground. The young pigs of the Chinese breed, especially the white variety, are excellent for roasters, at three weeks or a month old. They are small and fat, with little bone, and their skin is very delicate. They also make excellent porkers at about three months old, when kept for some time after weaning on the refuse of the dairy. They may be kept fat from the time they are weaned till they are fit to be killed for bacon; and although they do not come to a great size, they will pay very well for their food if killed at a twelvemonth old.

The breed that is nearest to the Chinese in this country is the Suffolk. They are generally white, with the ears pointed and rather forward. They are broad in the chest and loins, short, and compact: they make fine bacon hogs at twelve or fifteen months old, weighing from twelve to fifteen score when killed. The sucking-pigs and porkers are also very delicate. The Essex breed is mostly black and white. The pure breed however is quite black, and is so nearly allied to the smooth Neapolitan breed, which has scarcely any hair, that we cannot help supposing a consanguinity between them. When crossed with the Neapolitan they produce a breed which fattens at a very early age, and to an astonishing degree.

The Neapolitan hog is black, without any hair, very plump, with pricked ears. No breed can excel it in the aptitude to fatten. The sows often become so fat on very scanty food that they will not breed: they are extremely tender; and if they happen to have litters in winter, it is difficult to save the young pigs from dying in cold nights. A cross of the Neapolitan with some of our hardier breeds greatly improves their usefulness, without injuring their aptitude to fatten: the best cross is with the Berkshire, which is a very well shaped hog, with short legs, small ears, broad chines and loins, and good hams.

From the prolific nature of the hog it is not difficult to select the best individuals to breed from. In every litter there will be pigs better formed than the generality, and by careful selection of these any breed may be soon much improved without crossing; but experience teaches that when the sows and boars are too nearly related, the fecundity gradually diminishes; and by continually breeding from the same stock the sows at last produce only two or three diminutive pigs at a litter. Hence the advantage of frequent crossing. To restore fecundity no breed is so effectual as the Chinese. A breed compounded of the Berkshire, Chinese, and Neapolitan, may, by careful selection, produce every quality which can be desired: numerous litters, early fatting, and fine hogs for bacon at twelve or sixteen months old, are the result of care and judicious breeding.

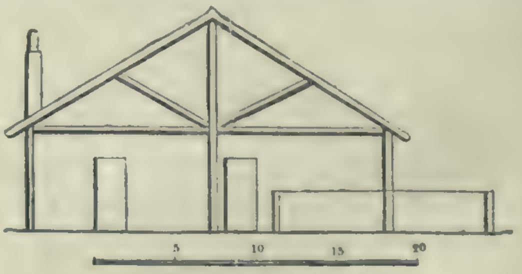
The black hogs are preferred on the whole. They are much less subject to diseases of the skin than the white, and the sun affects them less in summer. For sucking-pigs or porkers many prefer the white, merely for the appearance; for the black skin is in general the finest.

There are some very large breeds, which have been recommended under the idea that in a large hog the bone and offal are less in proportion to the flesh than in a smaller. But these large breeds do not come so soon to maturity. They cannot be profitably put up to fatten till eighteen or twenty months old, or more; and although some of them may make hogs of thirty or forty score when killed, they are so long fatting, and require so much food, that it is very doubtful whether they pay for it as well as the smaller. For delicate bacon the hogs killed at a twelvemonth old, and weighing ten or twelve score, are much preferred; and we are inclined to think that they are most profitable. When hams are the principal object the hogs should be killed before they are so fat as they might be; and the carcase is then cut up and pickled instead of being converted into dry bacon. To keep hogs profitably, a regular system should be pursued both in the breeding and feeding. Proper hogstyes should be constructed, with chambers in which the pigs of different ages and the breeding sows may be kept separate. The food should be prepared for them by boiling or steaming in an apparatus conveniently placed, and the greatest cleanliness and regularity should be maintained. It is a great mistake to suppose that the hog loves dirt. If he can keep himself clean he will do so; and the wallowing in the mud is not from a love of dirt, but from a heat and itching in the skin in warm weather, which is relieved by rolling in the cool mud. If hogs have plenty of clean straw and clean water they never will be dirty, and nothing makes them thrive so quick, or pleases them more, than being washed and curried regularly. If the hogs are not closely confined they will always lay their dung at a distance from the place where they sleep or feed, and in all well constructed styes there should be a small yard to each apartment, in which the hogs can deposit their dung.

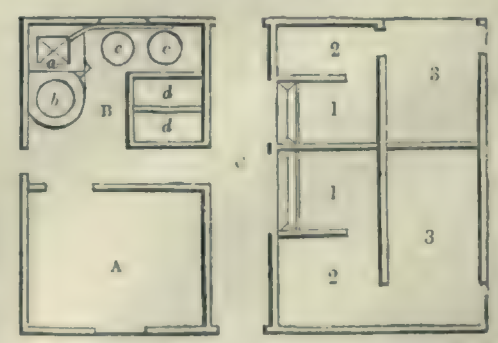
When a sow is near the time of farrowing, which is four months after she has taken the boar, she should be put in a stye by herself, with a moderate quantity of straw, for if there be too great an abundance she is apt to lie down on the young pigs when they bury themselves in the loose straw. Sows, although very careful of their pigs, are very apt to lie on them, especially when any of them are near a wall. To prevent this it is very useful to have a ledge of wood six inches wide and six inches from the ground all round the stye, so that she cannot lie down close to the wall; and if a young pig should be accidentally behind her he can take refuge behind the ledge, and thus escape being lain upon. When no precautions are taken, one-fourth of a litter is often lost in the first day or two after they are born. Some sows have the unnatural propensity of eating their young pigs as soon as they drop; good feeding will prevent this in some measure, but attention at the moment of farrowing is the safest and surest preventive. When once the young pigs have sucked, much of the danger is past.

A sow with many pigs should be well fed; bran and barley-meal with milk or whey is the best food; grains, where they are at hand, are excellent; and it is useful to let the sow go out to graze in a meadow or clover-field for an hour or two every day, shutting up the pigs during that time till they are a fortnight or three weeks old, when they may then accompany the sow. A sow will live many years and bring numerous litters, and the older she is the better nurse she is in general. When a sow has ten or twelve pigs at a litter, and two litters in the year, one in spring and another in autumn, she is too valuable to be killed, and ought to be kept as long as she will breed. But otherwise it is very profitable to let a young sow have a litter at ten months old, and spay her immediately; she will then fatten most readily as soon as the pigs are weaned, and the bacon will be as good as that of a maiden pig. Whenever a sow does not bring a sufficient number of pigs, or is not a good nurse, or has ever eaten any of her pigs, she should be spayed and fattened immediately. The young pigs intended to be kept for stores or for porkers, are castrated or spayed at a month or six weeks old. The males are then called *barrow* pigs, and when fatted make the best bacon. They are usually put up at a twelvemonth old, and fatted in three or four months. At first they have potatoes raw or boiled, mixed with bran, or bean-meal, or they have dry beans and water. After they are half fat they should only have pease-meal or barley-meal and water, unless in a dairy, where they have the skimmed milk or whey. Hogs fattened on potatoes only do not make so good bacon as those which are fatted on corn. This is the reason why the home-cured bacon sells so much dearer than the Irish. When a piece of raw bacon is put into the pot and swells in the boiling, it is a sure sign that the hog has been well fed; if it shrinks, it may be concluded that he has been fattened chiefly on potatoes. The labourers in the country, who live chiefly on bacon, know this well, and always purchase the best fed bacon, even at a much higher price, finding it most economical. Potatoes are an excellent food for store pigs, and may be given boiled and mixed with meal in the early part of the fatting process; but beans and peas make the firmest flesh, and barley meal the sweetest. Before a hog is killed he is usually fed for some time on barley meal and water alone, given as thick as porridge, and very little if any water is given to him. This last rule is often carried to too great an extent. Much water will make the food pass through too rapidly, and it will not be digested, but the hog should never suffer from thirst, or he will not thrive. Before a hog is killed he should be kept without food for twelve hours at least. He may however have water. He should be killed without giving him more pain or causing more struggling than is necessary, by a resolute stab with the knife in the lower part of the neck, where the knife may sever the large artery which comes directly from the heart. The blood should be allowed to flow freely till it is all out of the body. The hog, if intended for salt pork, must then be scalded with water not quite boiling, and well scraped to take off the hair with the cuticle; but for bacon it is best to singe the hair by burning straw over the body, and then scraping the skin. Care must be taken not to allow the skin to be burnt so as to crack. The hog is then hung up, and the entrails taken out. The inside of the body is washed clean with a cloth or sponge dipped in water, that no blood may remain, and the next day the hog is cut up. The head and feet are cut off; the chine is taken out, and the upper part of the ribs, with the backbone, are cut out, leaving as much flesh as possible adhering to the fat outside. The small ends of the ribs remain attached to the bacon.

Hog-stye.—Much of the profit of breeding and fattening hogs depends on the economy of labour in preparing their food. Any place is often thought good enough to lodge a pig in, and a stye is a word synonymous with a filthy place. But in every well arranged farm-yard there should be a convenient place for keeping hogs and feeding them, which may be erected at a small expense, and which will soon repay the outlay. There should be a place to boil and mix the food in, with one or more large coppers and a steaming apparatus. The food should be mixed in square brick tanks sunk in the ground and cemented, that there may be no filtrations. If there is only one tank, there should be a partition in it. From the boiling-house there should be an immediate communication with the feeding-styes, under cover, if possible. Each stye should open into a small yard behind, which should communicate by a door with the principal farm-yard, where the barn is situated in which the corn is thrashed, and be enclosed with a low wall or paling. There should be separate styes for breeding-sows, for porkers, and for fatting hogs. Not more than three or four of the latter should be in one stye. The food should be given in troughs, in a separate compartment from that in which the hogs lie down, and no litter should be allowed there. The floor, which should be of brick or stone, should be frequently washed clean, and the trough should be cleaned out before every meal; any of the food left from the last meal should be taken out and given to the store-pigs. A very convenient contrivance for keeping the troughs clean is to have a flap or door, made with hinges, to hang horizontally over the trough so that it



Elevation and Section.



A, root-house; B, boiling and steaming-house; *a*, steamer; *b*, copper; *c*, *c*, steaming-vessels; *d*, *d*, tanks to mix the food; C, passage to the styes; 1, 1, feeding-rooms; 2, 2, sleeping-rooms; 3, 3, yards.

can swing, and alternately be fastened by a bolt to the inside or outside edge of the trough. When the hogs have fed sufficiently the door is swung back and the trough is easily cleaned out. It remains so till feeding time, when the food is poured in, without any impediment from the greedy hogs, who cannot get at it till the door is swung back. This simple contrivance saves a great deal of trouble, and is easily adapted to any common stye. It is a great advantage to be able to inspect the styes without going into them, and this is effected by placing them under a common roof, which may conveniently be a lean-to to the boiling-house or any other building, with a passage between them.

The preceding figure will best explain this, and show its superiority over common styes.

HOGSHEAD, an ancient measure of liquids, which, not being mentioned in the act 5 Geo. IV., cannot now be considered as having any legal existence.

The hogshead of wine was 2 wine barrels, or 63 old wine gallons; the London hogshead of ale [Barrel] was 1½ ale barrels, or 48 ale gallons; the London hogshead of beer was 1½ beer barrels, or 54 beer gallons; and the ale and beer hogshead for the rest of England was 1½ barrels, or 51 gallons.

All Excise measurements being now made in gallons, the term hogshead remains in use only as the name of a large cask.

HOLLANDS. [Geneva.]

HOLY ORDERS. [Ordination.]

HOMAGE, an incident of tenure which is now abolished by 12 Car. II., c. 24. [Feudal System.] The word, according to Sir Edward Coke, is derived from homo, because when the tenant did his service to the lord, he said, "I become your man," &c.

Homage, according to the old English law writers, was of three kinds: by ligeance, by reason of tenure, and ancestral; the distinction between which is not necessary to state here: the whole subject, which is now merely matter of curiosity, is explained in 'Coke upon Litt.,' p. 64, and following pages.

The copyholders, or tenants who attend to do their duty in a court baron, are called *the homage*.

HOMBERG'S PHOSPHORUS. [Calcium; *Chlorine and Calcium.*]

HOMESTEAD. There is in most districts of the country a great difference between what is required as farm buildings by the intelligent farmer and what is supplied to him by the landowner. Every writer on agriculture has described what is wanted, but it is only here and there that you find specimens which come up to their ideal. Thus, Mr. Hewitt Davis, ('Practical Essays,') wrote many years ago the following description of a homestead:—

"On a well-arranged farm, the following details will have been attended to, namely:

"1st. The situation of the homestead will be central, and hard roads will have been made to afford free communication between it and all parts of the farm.

"2nd. The farmer's residence will have been so placed that he may see what is doing at the homestead, and have a constant eye on the labourers, the live stock, and property on the premises.

"3rd. The yards will be so protected by the stables, cattle-houses, and barns, that the stock will be sheltered from the east, north, and west quarters, and open only to the south, and so formed that the manure will be collected with least possible waste.

"4th. The barns will extend east and west, so that the sun at noon may shine on the barn floor, and their south side may form shelter hovels for the cattle to lie under.

"5th. The open cattle-sheds and pig-sties will face the south or west, so that the sun may shine into them, and the stock may lie dry and sheltered from the colder winds.

"6th. The rick-yard will be so situated as to have a quick and convenient connection with the barns, and be provided with rick-stands on pillars best adapted for ventilation and protection of the corn from vermin.

"7th. Tanks will have been made for the collection and preservation of the drainage from the stables, cattle-sheds, and yards.

"8th. A supply of water will have been provided, in convenient situations, for the ready and constant use of the animals.

"9th. Cottages will have been erected on the farm to secure a certain amount of labour at all seasons, and in situations where the labourers will lose little time in going to and returning from their labours, and may assist in the preservation of the property of the farm."

These memoranda will, with few exceptions, serve as a guide in almost every circumstance to what is wanted as a homestead. The tendency at present is to do away with barns, and to cover a given space of ground with shedding, dividing out the space thus sheltered into yards, or stalls, or boxes, according to convenience; but the references to position, aspect, accommodation, tanks, water, cottages, will be generally allowed as applicable everywhere. In illustration of the completer equipment which one sometimes meets with now on first-class farms, the following paragraphs are given as descriptive of the Coleshill farmery on Earl Radnor's home farm, the Englefield farmery on Mr. Benyon's home farm, and the Haineshill farmery on Mr. Garth's home farm, all in Berkshire. They are all more or less on the new system of a roof over the whole quadrangle on which the buildings stand.

1. *Coleshill Farmery.*—On entering the buildings, and the adjoining rick- and timber-yards, which you do at the east end, you find yourself in the barn, and in the upper story of it; for it is two stories high, the upper story being on a level with the rick-yard, and the lower on a level with the floors of the stables, cattle-sheds, and yards. This difference in the levels is caused by the site being on a declivity, which has been most judiciously taken advantage of, and by a little extra labour divided into two steps or flats, each with a very slight incline downwards, towards the west. In this upper story of the barn is placed part of the machinery connected with threshing and dressing the corn, weighing, and sacking it; also a mill, with a pair of French stones, for grinding wheat or other grain, either into fine flour, or for merely crushing it or kibbing it. There is, too, a mill for grinding linseed. Opening from this large floor is, on one side, a spacious granary, from which the corn, when dressed and sacked, can be let down, through a trap-door, by a chain and pulley into the waggons, to be conveyed away when sold. It opens also into the engine-house, and into a large loft for storing wool or anything else that requires to be kept dry. The threshing-machine, which, with all the other machinery, mills, chaff-cutters, &c., is driven by a steam-engine of 7-horse power, is placed on the ground adjoining to and on the same level with the upper floor of the barn, as is also a circular saw for cutting out rough stuff, which is likewise worked by the engine. All this machinery, including the steam-engine, was made and erected by Messrs. Clayton and Shuttleworth, of Lincoln. It is composed of various machines by which the grain is threshed, dressed, deposited in sacks, and weighed, ready for market, at one operation, without any intervention of manual labour. There is also a mill on an improved principle for grinding corn for cattle; also a chaff-cutter; a mill for bruising oats and linseed; a saw-bench with circular saw, &c., in the carpenter's shed: all of which are driven by a 7-horse power portable steam-engine outside the barn wall, which communicates the power to a line of shafting extending across the barn, from which the various machines are driven by leather bands. The straw passes down from the threshing-machine, on a sort of riddling screen, to the ground floor below (where the chaff-cutter is placed), either to be converted into chaff or to be stored away in the straw-house. Following it by a staircase, which leads down to the ground floor, the second flat or step of the area of the premises, you find yourself in a commodious building, with doors north and south large enough for a loaded waggon to pass through them. This building is appropriated for receiving the caving, chaff, and straw when cut for litter, being divided into separate rooms; the north end being reserved for the purpose of storing roots which are thrown in from the upper level through a shute provided for that purpose. The adjoining rooms are fitted up with various apparatus for steaming and preparing food for pigs and cattle, and comprise, as well, vaults for skim-milk, wash, &c., and a slaughter-house. On leaving this building by the south door, you enter a court in which, on your left hand, are the riding-horse stables, coach-house, harness-house, &c.; and above, and adjacent to them, the steward's office, room for reckoning with the men, &c. On your right hand is the building containing the boxes and stalls for the dairy cows, and the yards and sheds for these cows and their offspring, and for young stock. On leaving this building by the north door, another court is entered, which is surrounded by sheds for carts, ploughs, and other implements; by the cart-horse stables, harness-houses, &c.; and by the yards attached to some of the boxes for fatting cattle.

Returning to the centre of this building,—that is, to the spot, or near to it, where the straw from the threshing-machine comes out from the apparatus above,—and turning your face to the west, you look down a long vista, flanked on one side by the piggeries, and on the other by boxes for fatting cattle. The roof is of slate, with skylights, glazed with rough plate-glass, and open at the sides, which are fitted with ventilators. The roofs of the other avenues and of those parts of the building where the stock is kept confined are lighted and ventilated in a similar manner; thus every part of the place wears a light and cheerful appearance, and as there is free escape for all impure exhalations from the cattle and the litter, and as powdered gypsum is scattered about when and wherever necessary, the building is entirely free from any unpleasant smell. In the centre of this covered path, or main avenue, is a tramway which runs down to the tanks, and is to be continued on into the sheep-house, which is placed at the bottom, at the extreme west end. On passing along about two-thirds of this avenue, you come to a turn-table on the tram-way, the line being intersected here, at a right angle, by another avenue or transept, on which also a tramway is laid, which runs across the building from north to south, and on each side of which are cattle-boxes—the south end of it running into the building containing the boxes and stalls for the dairy cows. Leaving the main avenue at its western end (at the tanks), you cross a yard and enter the sheep-house, a spacious building at the extreme west of the premises, with an open railed floor, and pits underneath for the manure. Here there is ample room for about 400 sheep, for 250 or 300 ewes, and for 100 fat sheep, which latter are tied up at rack and manger. Right and left of this sheep-house and of the open yard between it and the tanks and manure shed, and occupying the south-west and the north-west corners or wings of the premises, are sheds and yards for young cattle, for 30 head of which there is ample room.

Returning from this point, and reaching the turn-table, you have, right and left, and before you, the cattle-boxes, 44 in number, intended for the use of 30 large beasts, each occupying an entire box, and 28 young beasts, standing two in a box. Turning to the right, you pass along the south branch of the transept, with cattle-boxes on each side of you, till you enter the cow-house, which occupies the centre portion of the south side of the premises. Here is room provided for 30 dairy cows,—20 in stalls, tied up, and boxes for 10, intended for the calving cows and their offspring. Attached to this department is the cow-yard, constructed to accommodate 14 cows, with room for 20 calves, on stages and boxes. There is also provision made for tying up 12 beasts, on the old stall-system, and for four bulls—two old and two young ones. On turning to your left, at the turn-table, on coming away from the sheep-house, you pass between the other end of the double row of cattle-boxes, and come out into the yard in front of the row of buildings composing the cart-horse stable (for 12 horses, with two loose boxes), harness-houses, sheds for implements, &c. &c.; these occupy one side, the north side of the yard; the west side being occupied by sheds and inclosed yards for young stock, colts, and for other purposes.

The piggeries are placed, as stated at the commencement of the description of the part of the buildings devoted to the reception of cattle, on your left hand as you proceed westward down the main avenue. They contain boxes walled in, for eight breeding sows and their young, for two boars, and for a score of fat pigs; each box having an inner and an outer compartment, or rather having an open yard attached to it, so that the inmates can enjoy themselves in the open air or under cover at will.

For this account of the Coleshill buildings we are indebted to the 'Wiltshire Independent.'

2. *The Englefield farmery.*—The buildings are centrally placed. They consist first of a block, about 50 feet by 100 feet, covered in by a double span roof, under which are 42 boxes—six single rows of seven each—the rows being separated alternately by three narrow gangways for feeding, and two wider gangways for carts entering to remove the dung. Each box has a manger for roots and hay and a trough for water. They are separated by rough paling, and the cattle are hindered from dirtying these troughs by a loose pole which they have to lift before they can get at their manger.

Another block of buildings of the same length includes threshing machines, granary, root-house, chaff-house, steam-house, and steam power (a fixed 10-horse engine consuming 8 cwt. a day of coals, and worked now about three days in the week). Between the two the space is roofed over and occupied as a straw house. The steam power is conveyed by strap to a longitudinal shaft upstairs, from which straps on pulleys carry it to the threshing-machine, turnip-cutter, two pairs of mill stones, two chaff-cutters, cake-crusher, and corn-bruiser.

The steam power is used to cut the roots for two days' supply by means of Samuelson's largest Banbury cutter, and to cut hay chaff at the rate of 5 tons in a day, two men feeding the chaff-cutter, and to crush oats and crack beans by Turner's capital machine for the purpose—all at one and the same time.

On the south side of this block of cattle boxes is a shed for implements. On the west side is a range of stables, lofty and airy, with no particular nicety, but great convenience, of internal arrangement, and on the other side as a lean-to there are shedding and yards for the calves, of which 50 or 60 are kept in three divisions, provided with racks for straw and mangers for the roots, and chaff, and cake. North of the threshing machinery and barns are six long rows of open roofing for storing away the corn. The implement shed, barns, straw house, granaries, and corn-shed thus succeed one another as you go northwards. East of this range is a cow byre, nag stalls, slaughter-houses, poultry-house, &c., on two sides of a square, thus sheltering a yard for cows and calves from the north and east, and lying alongside of the cattle boxes, and another square of pigsties and yards lying alongside of the granaries and threshing machinery. The corresponding space eastward of the rows of corn sheds remains to be occupied by sheds and yards for cows, if it should be resolved to establish a herd of short-horns. The threshing machinery was erected by Clayton & Shuttleworth, of Lincoln. The buildings were planned by Mr. Benyon and his steward, and erected by the workmen of the estate at a cost of about 3000*l*.

3. *The Haineshill farmery* has been erected from the plans of Messrs. Beadel and Chancellor, London, and their leading feature—extensive yards under lofty roofing—is more or less carried out at all the other homesteads which those gentlemen have erected on the estate. The main block of buildings occupies a ground plan of about 140 feet by 100. There is a lofty range on the long side, which runs north and south, and from the middle of this projects a shorter piece of the same height towards the east, while the main block is an extension for about 100 feet westwards of the same roof of its full length, generally, however, of a somewhat lower elevation. The lofty range includes in its centre a very complete threshing machinery, worked by a steam-engine of 8-horse power—all erected by Messrs. Ransome, of Ipswich. On the one side of this centre-piece lie the granaries above and cattle food stores with chaff house below; and on the other side lie hay and chaffing apparatus above and roots below. The hay is put in, from the cart or waggon outside, on the level of the upper floor, the roots are thrown in from the ground floor below. The corn to be threshed is thrown in on the upper floor at the end of the arm of the buildings which projects eastward; the ground floor of that piece being occupied by carpenters' shops. The corn fed into the machine on the upper floor passes downwards, the chaff is blown out below; the straw reappears, being lifted by the clever elevating shaker employed by Messrs. Ransome in their fixed barn machinery; and the corn being winnowed on its descent is brought upwards in elevators and passed through another winnower before it reaches the separators, from which it is delivered in sacks on the granary level. These are at once wheeled off to the stores, while the straw is carried away and stored on a floor on the same level, which extends under the higher part of the roof right over the covered yard below, from which it is thrown down for the supply of the yards.

From this floor you look down upon the yard below, and you see that the space is divided by three parallel gangways, extending westward from the north and south line of stores of chaff and roots. parallel with the sides of the yard. The two side gangways are about 4 or 5 yards from the side walls, the middle gangway extends down the centre of the intervening space. As you walk down one of these side gangways, you have on either hand the boxes in which the farm horses are kept solitarily, most complete in all their equipment with manger, water-trough, &c., only boarded up so high as to make it a case of complete solitary confinement except in so far as each has a look out on the gangway. As you walk down the other side gangway you have on one hand first boxes for cows, then little yards for sows with litters. On the other hand you have three yards each for six or eight cattle, either dairy stock, fatting beasts, or young and growing heifers and steers. The central gangway under the straw floor from which you see all this, has upon one hand a long range of sparred flooring divided into yards for ten or a dozen sheep each, and containing in all about three-score useful Hampshire Down tegs, evidently in thriving condition. On the other hand, and between you and the horse boxes, lies another series of yards for fatting cattle. The yards are sheltered on the north and east by the highest portion of the erection, and being also walled up on the sides to the roof, they are left for the most part open on the western side. The ridge lines of the roof are glass, and there is ample window room for light, so that light and ventilation are provided along with perfect shelter.

Apart from this main block of buildings lie the steward's house and out-houses, including an exceedingly neatly and even elegantly equipped dairy, a bake-house, slaughter-house, poultry-house and poultry yard.

The western and *open* side of the building presents a very tasteful elevation towards the mansion, which, at the distance of half a mile or more, presents its old Elizabethan gables amidst the wooded park.

On the same estate there are other good homesteads. Those at Hinton for instance, while evidently on a similar plan with that of the home premises at Haineshill, though on a smaller scale, are in some of their features superior. They, like the Haineshill ones, include yards open to the south sheltered by a lofty roof supported on slender iron columns and surrounded by a wall on the north side, and by a range of barns on the west, and of granaries, root-stores, chaff house, and stables on the east. The stables are thus open to the outer air, though well under the shelter of the roof, and the horses are arranged in pair stalls with swinging divisions. The central yard is surrounded by a gangway and includes divisions for cows, for fatting cattle, for calves and yearlings, with pens for swine. The floor is asphalte.

In addition to these descriptive notices, it must suffice to say, that the cost of good buildings is well repaid by the increased annual value of the estate. Shelter for live stock, and safety for produce, and for both cattle and implements, are always worth paying for; and the tenant of good land will not grudge as additional rent, a good per centage on the landlord's outlay in providing him with the necessary buildings.

HOMICIDE, in the English law, signifies the killing of one man by another. Homicide is of three kinds: justifiable, excusable, and felonious. Justifiable homicide is when the death is caused by the performance of an act of unavoidable necessity, where no shadow of blame can be attached to the party killing, as soldiers in action, persons defending their own lives, &c. Excusable homicide is of two kinds, by misadventure, and in self-defence; the first is where a man doing a lawful act, and using proper precautions, unfortunately kills another; the second, where a person in defending himself from an assault of a less serious nature than the second instance of justifiable homicide before mentioned, kills the offender; and this it is often difficult to distinguish from manslaughter, in the legal sense of the word.

Felonious homicide is the offence of murder; for the legal definition of which crime see MURDER.

HOMILY (ὁμιλία), in ecclesiastical writers, is a familiar discourse on a religious subject. In the earliest ages of the church the words *sermon* (λόγος) and *homily* appear to have been used indifferently; but Photius distinguishes the homily from the sermon, as being a familiar conversation, in which the preacher and people interrogated each other.

All the homilies of the Greek and Latin fathers were composed by bishops, for before the 5th century none but bishops were allowed to preach. We have good specimens of this sort of composition extant among the works of Chrysostom, Gregory, and other fathers. The

'Clementine Homilies' are supposed by Le Clerc to have been forge by an Ebionite in the 2nd century. (Lardner's 'Credibility,' pt. i, c. 29.)

In modern use the term "homily" is applied to a discourse read out of a book, and not composed by the preacher.

In the 8th century a collection of homilies was compiled from the writings of the fathers by Paul the deacon and Alcuin, at the command of Charlemagne. This collection is called the 'Homiliarium of Charlemagne.'

At the period of the Reformation in England two books of homilies were published by authority, in order to ensure uniformity of doctrine and to supply the defects of some of the clergy. The first book was published in 1547, and consists of twelve homilies, many of which are ascribed to Cranmer, and others to Latimer, Ridley, and Pilkington; the second, containing twenty-one homilies, supposed to be written by Bishop Jewell, was published in 1562, though composed earlier. They were appointed to be read in churches every Sunday, unless there were a sermon. These homilies are recommended by the 35th Article of the Church of England as "containing a godly and wholesome doctrine;" a list of them is given in the Articles appended to most Prayer Books; many of them are divided, so that in the whole there are forty-four discourses. Of the first book, which is less known, the following are the heads:—

1. A fruitful exhortation to the Reading and Knowledge of Holy Scripture; in two parts.
2. On the Misery of Mankind, and of his Condemnation to Death through everlasting, by his own Sin; two parts.
3. On the Salvation of Mankind, by only Christ our Saviour, from Sin and Death everlasting; three parts.
4. A short Declaration of the true, lively, and Christian Faith; three parts.
5. Of Good Works annexed unto Faith; three parts.
6. Of Christian Love and Charity; two parts.
7. Against Swearing and Perjury; two parts.
8. How dangerous a thing it is to fall from God; two parts.
9. An Exhortation against the Fear of Death; three parts.
10. Concerning good Order and Obedience to Rulers and Magistrates; three parts.
11. Against Whoredom and Uncleanness; three parts.
12. Against Contention and Brawling; three parts.

HOMŒOPATHY, the art of curing founded on resemblances, expressed in the Latin expression "similia similibus curantur." It is derived from the two Greek words "*ὅμοιος*" "similar," and "*πάθος*," "feeling" or sensation, and hence a condition of body, such as that of disease. According to this law, disease is cured by remedies which produce upon a healthy person effects *similar* to the symptoms of the complaint under which the patient suffers.

This system of medicine stands in direct contradistinction to that founded upon the principle of treating diseases by their opposites, "contraria contrariis curantur," which has served more or less as a guiding law since the time of Galen. To this last method the disciples of the new school have given the name of Allopathy, from the two Greek words "*ἄλλος*," "other," and "*πάθος*," "condition." This distinctive nomenclature will be adopted in this article as a matter of convenience, and to avoid circumlocution. The arguments adduced in support of the truth of the homœopathic law seem principally drawn from three sources, namely, from popular experience, from observations upon the effects of medicinal agents recorded in the works of eminent medical men of different schools and various epochs, and from experiments upon healthy individuals made by the founder of the system and his disciples upon themselves.

1st. Popular experience has proved that the safest manner of restoring the circulation of a frozen limb is to rub it with snow (similia similibus); warm applications, according to the evidences of the same experience, would cause the destruction of the part affected (contraria contrariis).

Again, severe burns are most quickly cured by the use of heated spirits of wine or oil of turpentine, which excite a very similar sensation, although in a greatly modified degree (similia similibus). Cold applications, although they give temporary relief, are, as is well known, generally followed by increased inflammation and severe after-suffering (contraria contrariis), as corroborated by the evidence of John Hunter, Kentish, Sydenham, and other medical names of high repute.

The homœopathists also insist that the acknowledged efficacy of Jenner's great discovery is a powerful argument of the truth of the homœopathic law, since by producing a similar disease an almost perfect immunity from attacks of the small-pox is obtained.

2nd. They endeavour to show by a number of observations collected from the works of different medical allopathic authors, that many drugs recorded by them as curative in different forms of disease were observed by others, also allopathists, to produce effects closely resembling the symptoms of those very forms of disease, or in other words, that they acted upon the principle, similia similibus: an instance or two will be sufficient illustration. The English sweating sickness, which committed such ravages in the year 1485, and for some time baffled the physicians, yielded, according to Willis, to sudorifics; and it is upon record that after the adoption of this mode of treatment very few died of it. Opium in general causes extreme drowsiness, heavy and deep sleep; and it has, according to the testimony of many allopathic physicians, proved curative in diseases characterised by similar symptoms. Moreover, it is asserted by the homœopathists that all the remedies acknowledged as specifics by the medical profession, of whatever school, act upon this law; for instance, they maintain that Peruvian bark produces medicinal symptoms closely analogous to those of marsh fever, and that the well-known efficacy of mercury in syphilitic complaints, and of sulphur in various forms of cutaneous disease, is attributable to the same power (similia similibus), and as above stated, that the action of vaccine matter, as a prophylactic or preventive medicine against small-pox, depends upon the same law.

3rd. Dr. Samuel Hahnemann, the founder of this system of medicine, being struck, as noticed in his life [HAHNEMANN in BIOG. DIV.], with the close analogy between the symptoms produced by Peruvian bark and those of the forms of disease for which it was considered a specific, and having obtained similar results from other medicines tried upon his own person, was led to the discovery of the homœopathic law; and he, believing that the mode of operation of all remedial agents was in perfect harmony with this principle, by repeated experiments upon himself and some medical friends, converted to his opinions, first determined their direct action and then employed them in disease. The practical results obtained by himself and the physicians of his school are appealed to by them as a further confirmation of the truth of their fundamental law.

The extremely minute quantities in which the remedies are administered, seem to form a marked difference between the homœopathic and all other schools of medicine. The homœopathists however assert that this is merely a point of practice to be determined by the physician at the bedside of his patient, and that in the application of the homœopathic principle to the treatment of disease, it was soon found that remedial agents given in the doses usually employed, acted too energetically upon a frame already predisposed to their influence by the affinity existing between their medicinal effects and the morbid signs of the disease; and hence a gradual diminution was made in the quantity of the medicine exhibited, in order to approximate to that amount which might exert its full curative power without aggravating the sufferings of the patient by an excess of medicinal action. The result has been, the general adoption among homœopathists of the minute doses at present in use.

Homœopathy numbers in its ranks many medical men who had obtained high repute and professional eminence in the other systems, before they embraced the principles of homœopathy, and seems to be more or less diffused in all parts of the world, if we may form any opinion from its literature, which comprises medical works in German, Italian, English, French, Swedish, Russian, Spanish, Latin, and Portuguese. The system has also adherents in North and South America and Asia. The great bulk however of the medical profession are more or less opposed to its adoption. This has arisen from the fact, that with an increased knowledge of disease and the action of medicines, there has been a tendency amongst medical men to discard all general theories of the nature of disease and the action of medicines. Although it is assumed by writers on homœopathy, that there is an allopathic theory, no well-educated medical man would adopt any such theory. The facts of homœopathic writers will stand even should their theory be forgotten; and it is to be regretted that the founder of this system, and his followers, have sought to impress their views rather as members of a sect than as men of science. The opposition which their views have experienced has been mainly due to this sectarian tendency. The question between homœopathists and other members of the medical profession, is rather social than scientific, a question rather of medical ethics, than of the interpretation of facts.

HOMOGE'NEOUS and **HETEROGE'NEOUS**, terms applied in mathematical language to expressions which have or have not the same number of factors of a given sort. Thus, with respect to x and y, $a x^2 + b x y + c x^2$ is homogeneous, but $a x^2 + b y$ is heterogeneous.

HOMOLACTIC ACID ($C_4H_4O_6$). A peculiar organic acid described by M. Cloëy as being produced in the manufacture of fulminating mercury. It is a colourless syrupy liquid of specific gravity 1·197, and is isomeric with *glycollic acid*. M. Dessaignes regards homolactic acid as impure glycollic acid.

HOMOLOGUES. [HOMOLOGOUS SERIES.]

HOMO'LOGOUS, a term applied in Euclid to those magnitudes which are both antecedents in a proportion, or which are both consequents. But when the four proportional magnitudes are all of one kind, the right of alternation empowers us to make and call any two terms homologous, of which one is an extreme and the other a mean.

HOMOLOGOUS SERIES. When the formulæ of the individual members of certain families of organic compounds are compared, it is found that these formulæ bear a very simple relation to each other, and that the individual members of each family differ in composition by two equivalents of carbon and two of hydrogen, or by some multiple of this number. The family of organic bodies to which common alcohol belongs affords an illustration of this graduated composition, as will be seen from the following table of the formulæ of these bodies:—

Methylic alcohol	$C_2H_4O_2$
Vinic alcohol (spirit of wine)	$C_4H_6O_2$
Propylic alcohol	$C_6H_8O_2$

Butylic alcohol	$C_8H_{10}O_2$
Amylic alcohol	$C_{10}H_{12}O_2$
Hexylic alcohol	$C_{12}H_{14}O_2$
Caprylic alcohol	$C_{16}H_{18}O_2$
Cetylic alcohol	$C_{32}H_{34}O_2$
Cerylic alcohol	$C_{54}H_{56}O_2$
Melissic alcohol	$C_{60}H_{62}O_2$

Such a family of organic bodies is termed a *homologous series*, and the members or terms composing it are said to be *homologues*, or homologous with each other. Whenever the formulæ of two neighbouring bodies in a homologous series differ from each other by a multiple of C_2H_2, a number of intermediate bodies, sufficient to fill up the missing step or steps in the graduation, must exist, and their subsequent discovery may be confidently predicted. Thus for many years the vinic and amylic alcohols in the above table stood next to each other, but the existence of the intermediate propylic and butylic alcohols was never doubted, although their actual discovery only took place very recently.

The following are the principal homologous series, or groups of series, which will be found described under their respective heads:—

Alcohols.
Anhydrides.
Ethers.
Haloid ethers.
Ethereal salts.
Organic radicals.
Hydrides of organic radicals.
Ketones.
Fatty acids.
Organic bases.
Organometallic bodies.
Amides.

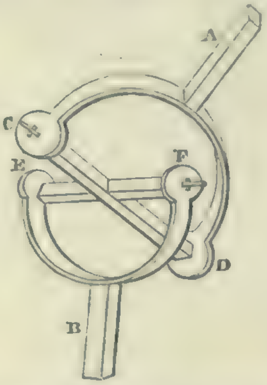
HONEY is a fluid or semi-fluid substance, the materials of which are collected by different kinds of bees, in Europe chiefly by the *apis mellifica*, or hive-bee, and solely by the neuter or working bees, from the nectariferous glands in the cup or chalice of flowers. It cannot be said to be a purely vegetable production, for after being collected by the proboscis of the insect it is transmitted to that distension of the œsophagus termed the crop, sucking-stomach, or honey-bag, where it is elaborated, and again disgorged, to be deposited in the cell of the honey-comb. It undergoes less change when the bees are very young, remaining nearly white, and is then denominated *virgin* honey. At all times it retains qualities derived from the kind of plant whence it has been procured, as is manifest not only by the peculiar odour of the honey, but by the effects which follow the use of honey obtained from certain plants, such as the Azalea, rhododendron, kalmia, &c., which yield a honey frequently poisonous, while that from the genus *Erica* (termed heather-honey), and most *labiate* plants, is wholesome. The soldiers of Xenophon, during the retreat of the Ten Thousand, suffered severely from partaking of honey collected by bees from the Azalea pontica near Trebizond.

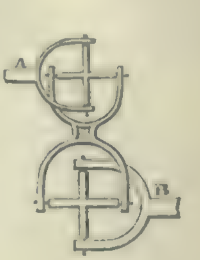
The honey of the common bee is at first generally white, inclining to yellow, but by age it becomes of a deeper colour and greater consistence, and of a more acrid taste. The honey of Surinam and Cayenne, collected by the *apis amalthea*, is red. The *apis unicolor* of Madagascar produces a greenish honey collected from the Mimosa heterophylla and Weinmannia glabra, of the most exquisite flavour. Honey is of different degrees of consistence: that of Mahon, of Hymettus, and of the Bermudas, is liquid; that of England is more or less disposed to become nearly solid.

Honey is sweet, faintly aromatic, granular, soluble in water, and capable of undergoing the vinous fermentation, and so yielding an intoxicating drink called hydromel, metheglin, or mead. Honey consists of an uncrystallisable portion, and a portion which crystallises in very white grains. The former is soluble in alcohol, the latter not, and is regarded as a sort of *Mannite*, or manna sugar, which, by the action of nitric acid, can be converted into oxalic acid, like the sugar of the sugar-cane. When old it probably contains some free acid. Honey is sometimes adulterated with flour, from which and other impurities it may be freed by diffusing it through cold water, or by striking the blue colour, indicative of starch, on adding iodine. Honey is certainly nutritive, but it cannot be employed to any great extent, since, if taken in considerable quantity, it excites the action of the bowels, and is gently laxative. Its effects in this way will be greater in proportion to its age and acridity, and less or scarcely appreciable if largely diluted with water. In this last state it is rather demulcent, emollient, and refrigerant, and hence forms a good drink in fever and other inflammatory complaints, but it should not be taken if there be much gastric or intestinal irritation. It is used likewise in catarrhs, and when drunk warm is considered to be expectorant. Along with vinegar it forms a good gargle in slight cases of sore throat, and combined with borax a most efficacious application in aphthæ of the mouth and throat. Owing to idiosyncracy in some individuals, honey causes great uneasiness, or even severe suffering, but it is most likely that such cases originate in the kind of plant from which the honey is collected, or in the measures used to destroy the bees. Smoking them with sulphur must be hurtful, from forming sulphurous acid gas, which may be absorbed by the honey. Humanity as well as economy demands that other means should be employed to procure the honey without sacrificing the life of the industrious insects which collect it. The fungus known as puff-ball, or Lycoperdon Bouesta, when smoked under the hive, stupefies the bees, as chloroform does men, so that the honey can be removed while they are insensible.

HONEY-TEA is nowise related to the foregoing. At the Cape of Good Hope this name is given to the infusion of the leaves and flowers of plants, growing abundantly on the sides of hills formed of variegated sandstone. These leaves and flowers are collected in great quantity by the poorer classes as a substitute for green tea. They are beneficial in diseases of the chest, which are, however, rare at the Cape. The plants are *Cyclopia galioides* (*D. C. the Aspalathus callosa*, Burn's 'Flora Cap.'); *C. genestoides, Goniphlobium maculatum* (Andrew's 'Bot. Repos').

HOOKE'S JOINT. Hooke's universal joint is a method of connecting two axes, the directions of which meet in a point, so as to transfer rotation from one axis to the other. The first figure represents the *single universal joint* in which A and B are the shafts between which the rotation is transmitted: C D, E F, is a cross the ends of which turn freely in bushes formed in the extremities of two diameters of semicircles in which the shafts terminate. If the shaft A be made to revolve B will evidently revolve also. If however the angle under the directions of the shafts be less than 140°, the motion will not be transmitted. In such case the *double universal joint* represented in the second figure must be used: this has two crosses, the extremities of which move on pivots like the former. These joints may be formed with a hoop or a solid ball instead of a cross, in which case four pins project at four equidistant points, so as to divide the circle in four equal arches, and the pins play in the bushes of the semicircles as in those of the cross.





The universal joint is much used in adjusting the position of a large telescope, where the observer has to turn endless screws or wheels, in a position inaccessible while the eye is being directed through the tube. This joint is also used in cotton and other mills where shafts are carried to a great distance from the prime mover, and it is an advantage to divide the shaft into convenient lengths, with a joint of this kind connecting them. The principle of Hooke's joint may be studied in the limbs of crustaceous animals and insects.

HOOPING-COUGH, or WHOOPING-COUGH. This disease, to which, on account of the violence of the cough that attends it, the Latin term "Pertussis" has been applied, and which from the recurrence of this cough in paroxysms has also obtained the popular designation "chin or kink-cough," appears to have been unknown to the ancients. No mention is made of it in the medical writings of the Greeks, Romans, or Arabians; but during several centuries it has prevailed in the various countries of Europe, and, from the frequency of its occurrence and the serious consequences of which it is sometimes productive, has much occupied the attention of physicians.

It commences with the symptoms of simple catarrh, and is indicated by cough and the expectoration of a clear limpid fluid, by redness of the conjunctivæ, a watery discharge from the eyes and nostrils, hoarseness, and occasional sneezing. These symptoms are attended by some degree of fever, which in general however is very slight; the patient is languid and out of spirits, but is free from pain, or complains only of soreness in the anterior part of the chest. During this stage the disease may be readily confounded with a common cold, but there is already some peculiarity in the cough, which occurs more in fits, and is more sonorous than in the latter malady. At the end of a period varying from one to two weeks the affection assumes a somewhat different character; the fits of coughing become longer and more frequent; each fit is commonly announced by a sensation of tickling in the larynx and trachea, during which the inspirations are irregular and incomplete, especially in children, whose countenances are at this time expressive of fear and anxiety. At the moment the fit comes on they cling with firmness to the persons or objects around them; if asleep at the time of its accession, they suddenly start up and place themselves in a sitting posture. The efforts of coughing are now repeated in such quick succession as to suspend almost completely the act of breathing: during their brief intervals we can with difficulty perceive any inspiratory movements, excepting at times when the cough is momentarily interrupted by a prolonged inspiration attended by a peculiar *whooping* noise, which has supplied a name for the affection, and which constitutes its characteristic symptom. In consequence of the obstruction to the circulation occasioned by these long continued efforts of coughing, the face and neck become swelled, and of a deep red or violet colour; the veins on these parts are distended almost to bursting; the eyes are prominent and bathed in tears; occasionally the patient becomes completely exhausted; the fit of coughing is interrupted for one or more minutes; it then recurs with the same violence, and the patient seems in imminent danger of suffocation, when the paroxysm is terminated by one or two long and *whooping* inspirations, and by the rejection of a limpid viscid fluid, which hangs in threads from the mouth, and to facilitate the discharge of which the patient inclines his body forwards. This fluid comes from the bronchi and pharynx, and sometimes also from the stomach; it is often mixed with portions of food which are rejected at the same time, and occasionally with particles of blood.

These paroxysms or fits of coughing continue for many minutes, and when they are very severe blood frequently issues from the nose, mouth, ears, or even from the eye-lids; they recur at various and often very short intervals, generally however more frequently and with greater severity by night than by day, and they are excited by the slightest causes, as by food or exercise, by any agitation or mental emotion. When the affection exists in a state of simplicity it is attended, even in this stage, with very little or no fever; the appetite continues as good as or better than in health, and the little patient, whose play was interrupted by the approach of the fit, immediately returns to it when the paroxysm is over; and during the intervals of these paroxysms often shows no other indications of disease than are furnished by the puffiness of the face and the redness and tumidity of the lips, which the interruption of the circulation during the violent and long continued efforts of coughing has occasioned.

In the intervals of the fits the chest sounds well on percussion, and on auscultation the respiratory murmur is heard pure, or mixed only with a little mucous râle on the posterior part of the chest, as in common catarrh. During the paroxysm breathing is almost completely suspended, and no respiratory murmur is audible except in the very short intervals which exist between the expulsive efforts of coughing; the prolonged and noisy inspiration which constitutes the pathognomonic character of hooping-cough seems to be limited to the larynx and trachea, and gives rise to no respiratory murmur audible on auscultation of the chest.

It is chiefly during this stage that hooping-cough becomes complicated with other diseases affecting the head or chest, on which its danger mainly depends. In children at the breast the most common complication is cerebral congestion, giving rise to convulsions; in persons more advanced in life the viscera of the chest become more frequently implicated, and it is to inflammation of the lungs and pleura that death, when it occurs, is generally attributable.

After the affection has presented the characters which we have described for a period which varies from two or three weeks to many months, the paroxysms become shorter and less frequent, and the cough ceases to be characteristic, but still continues to terminate in vomiting and in the discharge of sputa, which now resemble those of catarrh. The paroxysms become more and more rare, in some cases recur at regular intervals, and finally cease, but for some time afterwards they are easily renewed by any unusual exposure to cold.

The specific nature of the cough, and the insufficiency of the morbid changes noticed on dissection to account for the phenomena of hooping-cough, have led pathologists to seek for their interpretation in the condition of the pneumogastric nerves, but hitherto without success. M. Breschet indeed has in two cases remarked in these a redness externally, and a yellowness of their tissue, but no similar appearances have been observed by other physicians.

Hooping-cough prevails epidemically, and chiefly attacks children from birth to the period of second dentition, but it occasionally occurs in adult and even in old age. It rarely affects the same individual more than once, although this sometimes happens. It occurs in every variety of climate, and in all seasons, but is more general and more severe in cold than in tropical climates, and is most prevalent in seasons most favourable to catarrhal affections. It is of longer duration when it comes on in autumn or winter than when it makes its appearance in spring or summer; and like all other diseases that occur epidemically, it is much more severe in some years than in others.

Hooping-cough is one of those diseases that are communicable by contagion. It spreads very rapidly among children of the same family, and when it finds admission into a house very few of the young persons who have not previously had it escape; but they are protected from the disease if secluded from those previously infected. Hooping-cough is a very fatal disease, and the average annual mortality in London from 1849 to 1859 was 2190.

No method of treatment has hitherto been discovered by which the progress of hooping-cough can be arrested. We may mitigate its severity and somewhat diminish its duration, but it will run a certain course, and this course, in spite of all our efforts, will often be long. During the early stage of the disease the administration of emetics has appeared to be beneficial; in children they may be repeated every day, or every other day, for one or two weeks. Tartar emetic, on account of its solubility and the certainty of its operation, is the medicine best adapted to this purpose.

At a more advanced period of the disease great benefit is derived from the employment of narcotic and sedative medicines. Of these there is a great variety, each of which has had its advocates. We may particularly mention opium, hydrocyanic acid, belladonna, and Indian hemp; but on account of the powerful influence of these drugs on the system, the greatest caution should be observed in their administration to children. In some cases the administration of alum is particularly beneficial.

When the paroxysms are regularly intermittent, we may prescribe sulphate of quinine in the same doses, and almost with the same certainty of success, as in ague.

In protracted cases nothing is so efficacious in putting a stop to the cough as change of air, which often succeeds after all other means have been tried in vain.

At the commencement of the disease, and as long as any febrile symptoms continue, the diet should be of the mildest description; afterwards a more tonic and nourishing regimen may be allowed, not only with safety, but with advantage.

Cerebral congestions and inflammations of the lungs and pleuræ, when they occur during the course of hooping-cough, must be treated in the same manner as when existing under ordinary circumstances.

HOPFNER'S BLUE. [COLOURING MATTERS.]

HOPS (*Humulus lupulus* of Linnæus) are extensively cultivated for the flowers or seed-vessels, which give flavour and permanence to beer, by being boiled with the wort in brewing. They impart a pleasant bitter and aromatic flavour, and prevent the too rapid progress of fermentation. Beer which is well hopped will keep long and become very fine, without any of those artificial means of fining which make the common brewers' beer so much inferior in quality to that which is home-brewed.

Hops were introduced into England from Flanders about the year 1524. The most extensive plantations are in Kent, Sussex, and Herefordshire; but they are also cultivated in Worcestershire, Essex, Wiltshire, Hampshire, Gloucestershire, Surrey, and several other counties.

The hop is a slender climbing plant, which requires a very rich mellow soil and careful cultivation. It is very tender, and the produce is precarious, sometimes giving a great profit to the grower, and at other times failing altogether. The greatest quantity of hops is raised in Kent, but the finest quality in the neighbourhood of Farnham in Surrey. The soil of a hop-garden must be rich to a considerable depth, or made so artificially. The subsoil must be dry and sound; a porous rocky subsoil, covered with two or three feet of good vegetable mould, is the best for hops. The exposure should be towards the south, on the slope of a hill, or in a well-sheltered valley. Old rich pastures make the best hop-gardens. They should be dug two or more spits deep, and the sods buried at the bottom, where they will gradually decay and afford nourishment to the slender roots of the plants which strike deep. A very large quantity of the richest rotten dung, at least 100 cubic yards per acre, should be well incorporated with the soil by repeated ploughings, till it is entirely decomposed and produces that dark tint which is the sure sign of an abundance of humus. The ground should be prepared by laying it up with the spade in high ridges before winter, to expose it as much as possible to the mellowing influence of the frost. A succession of green crops, such as rye cut green or fed off with sheep, early turnips fed off in autumn, or spring tares, are an excellent preparation, by cleaning the land. It is better to be two or even three years in preparing the ground and getting it perfectly clean, than to plant the hops in a foul or unprepared soil.

The young plants are raised in beds, and may be raised from seed; but it is more usual to plant the young shoots which rise from the bottom of the stems of old plants. They are laid down in the earth till they strike, when they are cut off and planted in the nursery-bed. Care must be taken to have only one sort of hops in a plantation, that they may all ripen at the same time; but where there are very extensive hop-grounds it may be advantageous to have an earlier and a later sort in different divisions, so that they may be picked in succession. The varieties most esteemed are the Grape Hop, the White Vine, and the Golden Hop. The ground having been prepared for planting, it is divided by parallel lines, six or more feet apart, and short sticks are inserted in the ground along these lines at six feet distance from each other, so as to alternate in the rows, as is frequently done with cabbage-plants in gardens. At each stick a hole is dug two feet square and two feet deep, which is filled lightly with the earth dug out, together with a compost prepared with dung, lime, and earth, well mixed by repeated turning. Fresh dung should never be applied to hops. Three plants are placed in the middle of this hole six inches asunder, forming an equilateral triangle. A watering with liquid manure greatly assists their taking root, and they soon begin to show bines. A stick three or four feet long is then stuck in the middle of the three plants, and the bines are tied to these with twine or the shreds of Russia mats, till they lay hold and twine round them. During their growth the ground is well hoed and forked up around the roots, and some of the fine mould is thrown around the stems. In favourable seasons a few hops may be picked from these young plants in the autumn, but in general there is nothing the first year. Early in November the ground is carefully dug with the spade, and the earth being turned towards the plants, is left so all winter.

In the second year, early in spring, the billocks around the plants are opened, and the roots examined. The last year's shoots are cut off within an inch of the main stem, and all the suckers quite close to it.

The suckers form an agreeable vegetable for the table, dressed like asparagus. The earth is pressed round the roots, and the cut parts covered so as to exclude the air. A pole about twelve feet long is then firmly stuck in the ground near the plants; to this the bines are led and tied as they shoot, till they have taken hold of it. If by any accident the bine leaves the pole, it should be carefully brought back to it, and tied till it takes hold again. A stand ladder should be at hand to do this, when the bine has acquired some height. The ground being well hoed and the earth raised round the plants, the produce this year will average 4 cwts. per acre, if the season is favourable.

Some hop-planters plough up or dig the ground before winter; others prefer doing it in spring, in order not to hasten the shooting, which weakens the plants. The same operations of pruning the shoots, manuring, and placing poles, which were performed the preceding year, are carefully repeated. Particular attention is paid to proportion the length of the poles to the probable strength of the bines; for if the pole be too long, it draws up the bine, and makes it bear less: if it be too short, the bines entangle when they get beyond the poles, and cause confusion in the picking. In September, the flower containing the seed will be of a fine straw colour, turning to a brown; it is then in perfection. When it is over ripe, it acquires a darker tint. No time is now lost, and as many hands are procured as can be set a-picking; great numbers of men and women go out of the towns in the hopping season, and earn good wages in the hop plantations. During the picking they sleep in barns and outhouses. In the picking, the poles are taken down, and the stems cut 3 feet from the ground; if they were cut shorter it would weaken the root, by causing it to bleed. The poles are laid sloping over a frame of strong wood 9 feet long and 4 feet wide, supported by legs 3 feet high; this is called a bin. A piece of coarse cloth is fixed to this frame by hooks, so as to form a bag, which does not reach the ground. Three men or women, or four boys or girls, are placed on each side of the bin, and pick the hops from two poles at a time. Where they are very careful of the quality of the hops, as at Farnham, they divide them into three sorts: the green, which are not quite ripe; the light yellow-brown, which are in perfection; and the very dark, which are past their prime. Some go even further, and make several qualities according to colour and fragrance: for this purpose there are several baskets. The dew should be off entirely before they begin; for otherwise the hops might become musty, or take too long drying, and lose their fragrance. The hops when picked are dried on a hair cloth in a kiln. When they appear sufficiently dry at bottom they are turned; it is however thought by some hop-dryers that the turning of the hops is apt to injure them, and that it is best not to do so; but in order that the upper part may be dried equally with the lower, a wooden cover lined with tin plates is laid down over the hops on the hair-cloth, to within a few inches of the surface: this reverberates the heat, and the whole is dried equally. The heat must be carefully regulated, in order that it may not alter the colour. When the leaves of the hops become brittle and rub off easily, they are sufficiently dried. They are then laid in heaps on the floor, where they undergo a very slight heating. As soon as this is observed, they are *bagged*. This is done through a round hole 25 or 30 inches in diameter, made in the floor of the loft where the hops are laid. Under this hole is a bag, the mouth of which is drawn through the hole, and kept open by a hoop to which it is made fast. The hoop is somewhat larger than the hole, and the bag remains suspended; a handful of hops is now put into each corner of the bag, and there tied firmly by a cord. A bushel or two of hops are put into the bag, and a man gets into it to tread the hops tight. The bag does not reach the floor below. As the hops are packed by the feet, more are continually added till the bag is full. It is now taken off the hoop, and filled up with the hands as tight as possible. The corners are stuffed as soon as the mouth is partly sewn up, and tied as the lower corners were; when sewed close and tight, it is stored in a dry place till the hops are wanted for sale.

The crop of the third year will average 8 cwt. per acre. In some very extraordinary seasons, on good land, 15 cwt. have been picked per acre: in Flanders, where they manure with urine and the emptyings of privies, this is not an uncommon produce.

Rape cakes, malt dust, and woollen rags are used with good success in hop-grounds; bones have been tried, but with an uncertain result.

The hop is a diœcious plant, that is, some of the individuals are male plants, and others female, which have respectively flowers of a different construction and of different habitudes. Occasionally monœcious plants are met with, but these few are insufficient to fertilise all the female plants. The hops collected from bines in the neighbourhood of male plants are much larger, richer in aromatic and bitter principles, and a smaller proportion of such hops suffice to hop a given quantity of malt. The male or staminiferous flowers, which grow on stalks quite distinct from the female flowers, prepare the pollen, or fertilising dust, and afterwards wither away, when this dust has escaped from the anthers, and been committed to the air, to be by it conveyed to the female flowers. The female flowers are in the form of strobuli, or cones, consisting of scales, which have at their base the germ of the future seed, and which have the habit of enlarging, as the scales of the fir cones do, more particularly after the fertilisation of the ovule, or future seed, by a quantity of the pollen falling upon it. Though the pollen, from its extreme lightness, can be wafted to a considerable distance, and some seeds in each cone may be so fertilised, yet it would be well to rear a number of the male plants among the others, or along the hedges of the hop-gardens, to ensure the fertilisation of *all* the seeds. But as the farmers observe that the flowers of the male (termed, in Kent, seedling, blind, or wild hop; in Sussex, buck or cock hop) wither away, they generally extirpate them at the digging season, as unfruitful cumberers of the ground That this is an error may be proved in various ways, but an appeal to the result of an opposite practice is the most convincing. A bushel of hops, collected from plants of the fourth year, raised from seed, weighed 36 pounds, there being male plants near; a second instance, where the plants were raised from cuttings, weighed 35 pounds; while a bushel, grown in a garden where the male plants were always eradicated, weighed only 22 pounds. Besides the greater quantity of hops thus obtained, the aroma is much greater, and the strength of the bitter is much greater. After the period when the males have elaborated the pollen, and the strobuli of the females begun to enlarge, the males may be cut down, and the stalks employed to make cordage for hop-bags against the following harvest. In 1760 the Society of Arts awarded premiums for cloth made from the hop-bine. (Lance's 'Golden Farmer,' London, 1831.)

The poles are an expensive article; those of chestnut are the most durable, and also the dearest. They should be put into a shed during the winter: where this cannot be done, they are placed on end in the form of a cone, leaning against each other. If the top of these cones had a cap of thatch, it would greatly protect them from the weather: and it has been recommended to soak them in a solution of corrosive sublimate, according to Kyan's patent.

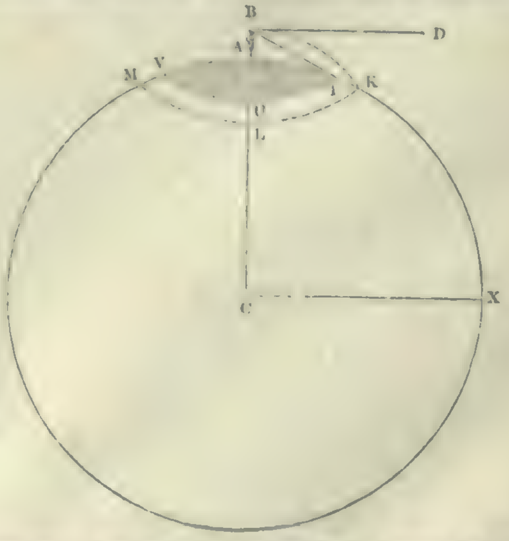
Besides the use of hops in brewing, they produce a bitter infusion and a tincture which are valuable in medicine for complaints in the stomach.

HORARY (Astronomy). The horary motion of the sun or a planet is the arc which it describes in one hour, or the angle which that arc subtends at the eye of the spectator.

HORDEIN. A substance extracted from barley, but which has been proved to be merely a mixture of starch and cellulose with a nitrogenous body.

HORDEUM DISTICHON (Linn.), *Medical Properties of.* The common summer barley is the kind directed in the Pharmacopœia to be used, but any of the finer sorts can be employed. Barley-water is either simple or compound: the former is merely a solution of the principles of the barley in boiling water; the latter has liquorice-root, figs, and raisins added. Both forms are demulcent and somewhat nutritious, and are useful in the treatment of mild cases of catarrh, or when acrid purgatives are taken, or when poisons have been swallowed. Barley is however an article of common consumption, either as an ingredient in soup or broth, particularly in Scotch broth, or as bread. It differs in some respect from wheat, in possessing less proteinaceous matter, and in having considerable bitterness in the husk. Farther, its starch is less soluble in water, and bread made of it is more difficult of digestion. It has, however, the advantage of being slightly laxative, and when it can be digested is a very proper article of diet for persons subject to habitual constipation. With a view to keep the bowels regular in infants, it sometimes forms as large as a fourth part of some of the prepared infants' food.

HORIZON (ὁρίζων, bounding). The physical horizon is the apparent circle by which the spectator's view is bounded when he is upon a level and uninterrupted plain, such as the surface of the sea. It differs from the astronomical horizon in two points: firstly, because the physical horizon *dips*, as it is called, or is not at the same level as the eye; and secondly, because the astronomical horizon always supposes the spec-



tator to be at the centre of the earth, and not at the surface. If A B represent a spectator standing upright, and C the centre of the earth, then, if the circle V A X revolve round the axis B C, the physical boundary is the circle described by T, or T U V, and the astronomical horizon is the plane traced out by C X (indefinitely extended) drawn parallel to B D, or perpendicular to C B; and the angle D B T is called the *dip* of the physical horizon. In consequence, however, of the refraction of light, by which the rays are curved, as in the dotted line drawn from B, the physical horizon is thrown farther than in the explanation just given; for instance, to the dotted circle K L M. The effect of this is to make the distance A T greater by about its twelfth part. The rough rule for finding the distance of the apparent horizon at sea is—$1\frac{1}{10}$ of the square root of the height of the spectator's eye, *in feet*, gives the distance of the physical horizon *in miles*. Thus, at a height of 100 feet, the horizon is 13 miles off.

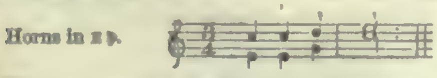
The astronomical horizon divides the heavens into a visible and invisible part. Properly speaking, it is the physical horizon which does this; but the distance of the fixed stars is so great, that the magnitude of the whole earth is but as a point, and the planes traced out by the revolutions of B D and C X may be confounded. It is not precisely the same thing with the planets, and least of all with the moon; but this belongs to PARALLAX. For the general use of the astronomical horizon, see SPHERE, DOCTRINE OF THE.

The plane of the horizon at any place is perpendicular to the direction of a plumb-line, or parallel to the surface of any fluid at rest. At sea, when it is necessary to take the altitude of any heavenly body, the physical horizon is, in tolerably fair weather, sufficiently well defined for the purpose, and, with proper allowance for its dip, is used accordingly. But in land observations with a sextant or other instrument requiring an horizon, the surface of a fluid (generally mercury) is used, which is called an *artificial horizon*, but might more properly be termed an artificial portion of a horizontal plane. A very slight knowledge of optics [REFLEXION] will show that the angle subtended at the eye by a star and its image in a fluid is double of the star's altitude: this angle, then, being measured and halved, the altitude of the star is found.

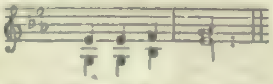
HORN, a musical wind instrument, which in its primitive state (that is, formed of the horn of an animal, or simply a shell) has been known from remote ages. Of the horns now in use, three are correctly denominated,—the *French horn*, the *bugle-horn*, and the *Russian horn*. These are made of brass. The *basset horn* (*corno bassetto*), and the *English horn* (*corno Inglese*), formed of wood, and partaking in no respect of what is generally considered the distinguishing character of the horn, seem to be improperly named.

The *French horn*, or now, *par excellence*, the *horn*, is a tube of about ten feet, very narrow at top, widening considerably at the bottom, and bent in rings for the convenience of the performer, as well as to render it more portable. It is not provided with holes, as the flute, &c., the production of the various sounds depending upon the lips of the player, the more or less pressure of his breath, and the insertion of the hand in the bell, or wide end, of the instrument. As a simple tube, the horn, governed by the laws of acoustics [ACOUSTICS], yields only the generating note, or tonic, and its aliquot parts, or harmonics, and, of course, would be confined to one key, but for the contrivances just mentioned, by which the length of the instrument is adjusted to the key required. This consists in *crooks* and *shanks*, or shifting pieces, added as wanted to the upper end of the tube; and thus the horn may be employed in all keys.

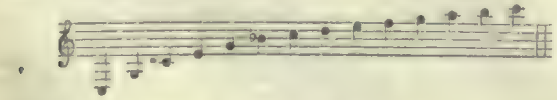
Music for the horn is always written in the key of C, an octave higher than played, and in the treble clef; and the key in which the instrument is to be tuned is indicated by the composer. Thus, if the piece be in E♭, the words "*corno in E♭*" are prefixed to the horn part. Example, as written:



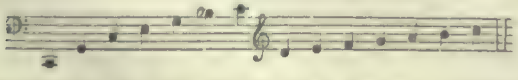
The notes actually played are—



The natural scale of the Horn is that of the trumpet, but an octave lower. It is written as follows:—

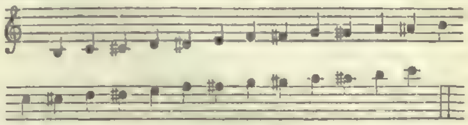


But the following are the sounds really produced:—

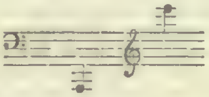


By introducing the hand into the *bell* of the horn, a tolerably good semitonic scale can be produced; and by the addition of two valves to the instrument, the performer can command a still more perfect scale of semitones.

The *bugle-horn* is a tube of three feet ten inches in length, doubled up in a small compass. The *keyed bugle*, or a bugle-horn with keys, is that now in common use, the scale of which is as follows:—



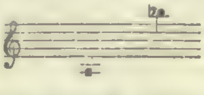
The *Russian horn* is an unbent brass tube, conical in shape, of various dimensions: the deepest toned is eight feet long and nine inches in diameter at the wide end, and the highest is two inches and a half in length, by one at the wide end. The former gives A, an octave below the first space in the bass; the latter gives E, the third additional line above the treble; or—



Some of these horns, though not all, have keys, producing one or two semitones; but generally every note has its separate horn, and a band of Russian horns counts almost as many individuals as diatonic notes in a scale of between four and five octaves.

Basset-horn, or *corno bassetto*. [BASSET-HORN.]

The *English horn*, or *corno Inglese*, is a deeper-toned oboe, but of rather larger dimensions, somewhat bent, the lower end very open, and is to the oboe what the basset-horn is to the clarionet, or what the viola is to the violin. The tone of this instrument is extremely pathetic, and by the Italians is thought so much to resemble the human voice, that they sometimes call it the *voce umana*. The scale of the *corno Inglese* (by which name it is most commonly known by musicians) is from A below the treble staff to B♭ above, or—



including all the semitones, except the lowest A♯.

Of late years M. Adolphe Sax, of Paris, has excited much attention for his *Sax-horns* and *Sax-trumpets*, which have had considerable influence on military music. It is stated in the Jury Report (class X A), that "his *Sax-horns* (double bass in E flat, and B flat) have left ophicleides very far in arrear; and his small treble Sax-horn in B flat is the only brass instrument known that can reach with certainty and just intonation the notes of the upper octave of the flute. His cornets-à-pistons are the best we are acquainted with. M. Sax has also created the class of *Saxophones*, brass instruments with a simple reed, similar to the clarionet. The effect of these new instruments possesses a charm equal to the originality of their tone, and they carry to the highest degree of perfection '*la voix expressive de l'orchestre*.'" Favourable mention is also made of his bass and double bass clarionets, in wood and metal. He has likewise filled up the gap in the tenor trombone, between the lower E and the lowest B flat; and his brass *bassoon* is very perfect. He has also contrived a means of continuing the sound in brass instruments from one note to another through all the enharmonic intervals; and he has invented a means of changing, by means of portable tubes, the monotonous character of the simple bugle, and giving it the power of producing all the intervals of the musical scale.

HORN MANUFACTURES. It is customary in England to use the same word to denote two quite different substances; namely, the branched bony horns of the stag genus; and the simple laminated horns of the ox genus and other kindred genera. The purposes to which the first of these kinds is applied are the same as those of bone and ivory, and the manufacture presents the same similarity. The other kind of horn, to which the French appropriate the name *corne* (while they apply the name *bois* to bony horns), is found in the ox, the antelope, and the goat and sheep. The structure of such horns may be described as a number of conical sheaths inserted one into another, the innermost lying upon the vascular membrane which covers the bony core. The tip, or that portion of the point of the horn which projects beyond the core, is very dense, and the several layers of which it is composed are scarcely distinguishable; while towards the base the layers may be readily distinguished, owing to their successive terminations forming prominent rings. Horn appears to consist of coagulated albumen; and there is a graduated connection between the substance of horns, nails, claws, hoofs, scales, hair, feathers, and even skin.

The principal kinds of horn employed in manufacturing operations are those of oxen, to which the hoofs of the same animals may be added. The horns of bulls and cows are preferred, those of bullocks being thin and of a coarse texture. The horns of goats and sheep are preferred, as being whiter and more transparent than those of any other animals. The first process in the manufacture of horn is to remove the bony core or pith, which is accomplished by steeping the horns in water for a month or more; by this operation the membrane which lies between the core and the horny sheath is so softened by putrefaction that the cores may be easily extracted. These are not thrown away, but are burnt to ashes, in which state they form the best material for the small tests or cupels employed by assayers of gold and silver. In some cases, instead of being thus used, the cores are boiled down in water, by which a quantity of fat is extracted, which, rising to the surface, is skimmed off and sold to the makers of yellow soap; while the liquid itself is used as a kind of glue, and is purchased by cloth-dressers for stiffening; and the remaining insoluble substance is crushed in a bone-mill for manure. The solid tip of the horn is sawn off with a frame-saw, and is employed for making knife-handles, umbrella-handles, the tops of whips, buttons, and various other articles. The remainder of the horn, employed for purposes for which thin laminæ are required, may either be left entire, or sawn into two or more lengths, according to the use to which it is to be applied. When divided the lower part, or that next the root of the horn, is frequently employed for making combs, while the portion which has formed the middle of the horn is used for lanterns and similar purposes. To prepare the horn for use, it is immersed in boiling water for about half an hour, by which it is softened; and, while hot from this operation, it is usually held in the flame of a coal or wood fire, until it acquires about the temperature of melting lead, and becomes so soft as to be semi-fluid. If the horn be from an old animal, care is taken to expose the inside as well as the outside to the action of the flame. Sometimes the softening is effected by pressure between two heated surfaces of iron. The slitting of the horn is performed while it is in the semi-fluid state, by a strong pointed knife resembling a pruning-knife; and, by the application of two pairs of pincers, one to each edge of the slit, the cylinder or cone of horn is opened until it is nearly flat. Several pieces are then exposed to pressure between alternate plates of iron, previously heated and greased, either in a press, or by placing them vertically in a strong iron trough, and compressing them by means of wedges. The degree of pressure applied depends on the proposed use of the horn; if it be intended to form very thin leaves for making lanterns, the pressure should be sufficiently strong to break the grain, or cause the laminæ of the horn to separate a little, so that the edge of a round-pointed knife may be inserted between them to complete the splitting or separation. The thin sheets of horn are then scraped with a blunt or wire-edged draw-knife, upon a board covered with bull's hide; and when thus smoothed and brought to the required thickness, they are polished by a woollen rag dipped in charcoal dust, a little water being added from time to time. They are afterwards rubbed with rotten-stone, and finally with horn shavings. The painted toys known under the name of Chinese sensitive leaves, which possess the curious property of curling up as if they were alive when laid upon a warm hand or near a fire, are made of the best of the thin films removed by the draw-knife. When the horn is to be converted into combs, the pressure applied in flattening must be as slight as possible: lest, by the breaking of the grain, the teeth of the comb become liable to split at the points. If a comb or any other article be required of greater size than can be made out of a single plate of horn, two or more may be united by the dexterous application of a degree of heat sufficient to melt but not to decompose the horn, assisted by pressure. When this is well managed, the junction cannot be perceived. The Chinese are skilful in this kind of work, as may be seen in the large globular lantern in the museum at the East India House, about four feet in diameter, composed entirely of small plates of coloured and painted horn.

Horns for combs are roughly cut by a hatchet or saw to the required shape, and then finished by rasps and scrapers. If required to be of a curved shape, they are first made flat, and after the teeth are cut they are softened in boiling water, and pressed until cold in a die of hard wood. Horn combs ornamented with openwork are extensively imported from France, where they are produced by pressure in steel dies. Horn shavings, when heated to a soft state, may easily be pressed into the form of combs, snuff-boxes, and other articles. The mode of cutting the teeth of combs is described under COMB MANUFACTURE.

Drinking-horns are now made by sawing the horn to the required length, scalding and roasting it over the fire, placing it while hot in a conical wooden mould, and driving a wooden plug firmly into the interior, to bring it into accurate shape. When cold and hard, it is fixed on a lathe, and turned and polished both inside and outside; and a groove or *chime* is cut with a gage-tool within the smaller end, for receiving the bottom. The horn is then softened before a fire, and the bottom, which is a round flat piece of horn cut out of a plate with a crown-saw, is dropped in at the larger end, and forced down until it reaches the chime. By the subsequent contraction of the horn in cooling, the bottom is so firmly fixed as to be perfectly water-tight.

In the manufacture of all articles made of fragments of horn compressed into a solid mass, great care is necessary to avoid the presence of grease, which would prevent perfect union. The masses of horn should be moved with wooden instruments while at the fire, and in carrying them to the moulds. Bell-pulls, the handles of table-knives and forks, knobs for drawers, and many other useful articles, are thus formed: care being taken, whenever the article is put into the mould in two or more pieces, to fit them together so that they may dovetail one into another.

Horn is easily dyed of various colours. In this country it is usually coloured of a rich reddish brown, and spotted to imitate tortoiseshell; this is effected by a mixture of pearl-ash, quicklime, and litharge or red lead, with water and a little pounded dragon's blood, applied hot to the parts of the horn which it is desired to colour. For a deeper colour the mixture may be applied twice; and for a blacker brown the dragon's blood may be omitted.

No part of the refuse of the horn manufacture is without its value. When exposed to a decomposing heat in close vessels, horn produces a large quantity of the gaseous compound which forms the base of prussic acid: on which account hoofs and horn cuttings are in great request among the manufacturers of Prussian blue, and of the beautiful yellow prussiate of potash. The clippings of the comb-maker are also used as manure. In the first year after they are spread over the soil, they have comparatively little effect; but during the next four or five their efficiency is considerable. The shavings of the lantern-maker, from their extremely thin and divided form, produce their full effect on the first crop.

Two recent improvements in the horn manufacture may be briefly noticed. One, introduced by M. Possoz, of Ixelles, in Belgium, consists in so heating, pressing, and rolling the horn, that the grain becomes straightened, the fibres lengthened and compressed, and the substance rendered so elastic and solid as to be fit for making into the ribs of umbrellas. Another, by Mr. Macpherson of Sheffield, relates to the manufacture of articles of furniture out of small waste fragments of horn and hoof. He cleanses the fragments from grease and dirt, soaks them in boiling water containing a little lime and potash, brings them into a cohesive mass by pressure between iron dies or moulds heated to 300° Fahr., and finally gives shape to them by pressure in moulds specially prepared. The finer the fragments, the better the result; if there be differences in quality, the best is kept at the surface. Varied effects may be produced by cementing different colours and kinds together; and inlays of mother-of-pearl or of metal may be used. Horn dust is better than any fragments; and one pound of horn will yield twenty-two cubic inches of such dust. The substance produced is well suited for table-tops, panels, work-boxes, dressing-cases, door knobs, &c. Hoof works up nearly as well as horn, and looks much like tortoiseshell. A table-top has been produced, of twelve square feet, and three-quarters of an inch thick, with forty pounds of horn. The solid tips of horns are worth 30*l.* a ton, but waste horn can be bought for a quarter of this price; and this relative cheapness appears to have suggested the mode of manufacture here described.

The manufacture of a kind of artificial horn has been established in France. It consists of gelatine, usually obtained from bones by treating them with muriatic acid, converted into a horny substance by tanning. Upon becoming hard and dry it resembles horn or tortoiseshell, both in appearance and in the facility with which it may be softened, by boiling in water with potash, and moulded to any required form. By inlaying with gold and silver, and staining with various colours, it may be rendered highly ornamental.

A considerable trade in horn has sprung up. The importations exceed 3000 tons per annum, the chief supply being from the East Indies. The importations in one year into Liverpool comprised 280 tons of deer horns, 200 of buffalo horns, 120 of buffalo tips, and 700 tons of ox and cow horns. Including the produce of home animals, the quantity of horns worked up is supposed to be not less than 6400 tons, worth 180,000*l.* The comb manufacturers alone consume 1300 tons, which produce 320,000*l.* worth of combs. Sheffield requires nearly 300,000 deer horns annually to make handles for cutlery.

HORN-WORKS AND CROWN-WORKS, are fortifications usually situated in advance of the principal works of a place. The rampart of the front, on the plan, is similar to that which is formed on each side of the polygon, supposed to surround a regular fortress; and on each flank a line of rampart returning from the nearest extremity of the front terminates on the ditch either of a bastion or ravelin on the enceinte of the place. The work is generally strengthened by a ravelin placed before the curtain between its two demi-bastions, and by a covered-way and glacis beyond the ditch; these return along the branch or wing on each side, and join the covered-way and glacis of the collateral bastion or ravelin of the enceinte.

The invention of horn-works is referred to the commencement of the 17th century. At first the plan of their rampart had simply the form of the letter M, the upper points being directed towards the country like horns; from which circumstance the work obtained its name. They appear also to have been at first formed of earth only, for the purpose of strengthening a place in daily expectation of a siege, when there were no outworks and when the bastions were small and very distant from each other. They were then constructed in front of the curtains, by the fire from whence the approach of the enemy towards their flanks might be opposed.

But the feeble defence which was made by such works when attacked in front, and the advantage of occupying beyond the principal fortress some position from whence, during the siege, the enemy might be annoyed in forming his approaches, or which, if gained by the latter, might enable him to command the town, almost immediately induced engineers to give to the horn-work the form first described, and to extend it considerably towards the country. Being however regarded but as a work of secondary importance in the defence of a place, the length of its front was seldom so great as that of the sides of the polygon on which the fortifications of the enceinte were constructed, and generally did not exceed 240 yards; which, since the relief of its rampart was necessarily nearly the same as that of the enceinte, scarcely allowed the ditch before its curtain to be effectively defended. The lengths of the branches or wings were regulated by the necessity of having the ditch and covered-way in front of the salient angles of the demi-bastions within the range of a fire of musketry from the collateral works towards which the ramparts of the wings were directed; and occasionally the latter were broken, on the plan, so as to form short flanks from whence a fire might be directed towards the nearest of those salient points.

That which has been found occasionally useful is too frequently, by an improper application, converted into a positive evil; this was the case with the works now being described; and at a very early period the multiplicity and injudicious disposition of them were subjects of animadversion among the best engineers. It often happened that they were constructed at great expense in situations where no end whatever was to be gained by them, and so close together that the defenders of their branches could not have avoided firing upon one another.

In proportion as the means employed in the attack of places were increased the earlier fortresses became incapable of affording room for the buildings necessary to lodge the troops, and contain in security the quantity of artillery and stores which the corresponding augmentation of the means of defence demanded; and hence it was sometimes found necessary to increase the extent of the advanced works about a place. This was done, at first, not by enlarging the dimensions of the half-bastions and curtain at the head of such works, but by making that head to consist of two or more fronts of fortification, in which case they took the name of double, triple, &c., horn-works, but more generally CROWN-WORKS. At a later time however the importance of advanced works was more highly appreciated; and, both by an improved disposition of them and by giving to their fronts dimensions equal to those of the general fronts of the place, they became not only free from the defects to which the old works were subject, but also capable of making a defence equal to that of a regular fortress.

The defects of the old horn-works consist in the expense of the construction being greater than is warranted by the benefit to be derived from them in the defence; in presenting to the enemy a front which, from its smallness, may be taken more easily than one of the fronts of the enceinte; in the revêtment of the latter being liable to be breached by a fire of artillery directed along the ditches of their wings from batteries formed on the glacis opposite the salient angles of the work; in the comparative security with which an enemy, after having made a lodgement in the work, might carry on his approaches in the interior in consequence of the protection afforded by the ramparts of the wings against any attempt of the besieged to impede him by sorties directed upon his flanks; and, lastly, in the large place d'armes the ditches afforded in which the assailants might assemble in large numbers unnoticed and in security for an assault. It should be observed, however, that Vauban, who constructed many such works, appears to have entertained a favourable opinion of them. He gives the preference to such as are formed immediately in front of a bastion; the wings being directed neither to that work nor to the collateral ravelins, but towards the curtains adjacent to the bastion. By this means the ditches of those wings are capable of being defended by the artillery of the curtains, while the revêtments of the latter are covered by the tenailles so as to render it impossible to breach them near the foot by a fire of artillery directed along those ditches. But his best application of a horn-work was made at Belfort, where he executed one entirely in advance of the glacis of the place; in consequence of this disposition the revêtment of the enceinte is effectually secured against being breached till after the horn-work is taken; while, at the gorge of the latter, the height of the terreplein above the ground at the foot of the glacis ensures the work itself from being taken by an assault in that direction.

A nearly similar disposition was adopted by Cormontaingne in executing the double crown-work at Metz. Beyond the glacis of that place, on one side, the ground rises with a gentle inclination, till, at some distance from thence, it forms one side of a deep valley; and along the brow are constructed, on nearly a straight line, three strong fronts of fortification. The ground is terminated on the left by an escarpment, which is crowned by a line of rampart with its covered-way and glacis; and on the right is a valley watered by a rivulet, which, being dammed, forms a lake capable of securing the works against an attack on that side. Each flank is further protected by a detached lunette, or redoubt: that on the right, being surrounded by water, is nearly inaccessible; and that on the left is strengthened by a system of counter-mines.

The ample capacity of the bastions and the direction of their faces, which are such as to prevent them from being enfiladed; the contraction of the ground before the works, by which the enemy would be reduced to the necessity of making his attack on a smaller extent of front than that of the defenders; and finally, the measures taken to secure the flanks, justly entitle this fortification to the character of being the most complete of its kind in Europe.

HORNPIPE, a rustic musical instrument, still, we believe, known in Wales, consisting of a wooden tube, with holes, and a reed. At each end is a horn; one to collect the wind blown into it by the performer, the other to augment the sound. The Hon. Daines Barrington states, ('Archæologia,' vol. iii., 1770) that "the tone, considering the materials of which the instrument is composed, is really very tolerable, and resembles an indifferent hautbois." In the Welsh language its name is *pib-corn*, which signifies, literally, *pipe-horn*. Sir John Hawkins quotes Chaucer to show that the hornpipe was a real, not an imaginary instrument; but in the 'Tatler,' No. 157, is a proof not only of its reality, but its actual existence so late as 1710.

Hornpipe is also the name of a dance; and Barrington is of opinion, that the dance-tunes called *Hornpipes* were originally composed for the instrument known by the same name. Hawkins says, that the hornpipe was invented in this country. It appears,—from the 'Dancing-Master,' 17th edit. 1721,—to have been in triple time, six crotchets in a bar; but the well-known tune, *The College Hornpipe*, is in duple measure.

HOROLO'GIUM (Constellation), the Clock, a southern constellation of Lacaille. It is cut by a line passing through Canopus to the southern part of Eridanus. Its principal stars (of which it is not worth while to make a table) are α and β, 34 of Piazzi and 229 of Lacaille, or 1315 and 956 of the 'B. A. Cat.,' both of the fifth magnitude.

HOROLOGY (from the Greek ὥρα, time or hour, and λόγος, a discourse), is an explanation of the principles of the measurement of time; but in its modern sense the term is usually applied as descriptive of that art which comprehends a knowledge of the action of the various machines used for the purpose of measuring time.

Sun-dials, which show apparent time, and clepsydræ, which give a rude approximation to mean time, were the earliest machines used in the measurement of time. [CLEPSYDRA; SUNDIAL.] We shall in this article only treat of those pieces of mechanism, used for the measurement of time, which are kept in motion either by the constant action of gravity through the medium of a weight, or by the elastic force of a spring, and which have received names varying according to the duties they have to perform. Thus, the term *timepiece* is applied to any piece which is intended merely to mark the time without striking the hour; a *clock* is one which, in addition to showing the time, strikes every hour, on a bell or spring, a number of strokes corresponding to the hour of the day or night indicated by the hands at the time; a *quarter clock* is one which also strikes the quarters as the hand successively arrives at them; a *watch* is a pocket timepiece; and a *repeater* is a watch which by means of any mechanical contrivance can at pleasure be made to repeat the hour, or hour and quarters.

History of Clocks and Watches.—The early history of clocks and watches is enveloped in so much obscurity, that it would be almost impossible to point out any individual who could with propriety be called the inventor. The term *horologium* was used very early in different parts of Europe; but this word being formerly applied indiscriminately to a sun-dial, as well as a clock, nothing decisive can be inferred from its use. Striking clocks were known in Italy as early as the latter part of the 13th or beginning of the 14th century. A fine imposed on the chief-justice of the King's Bench in 1288, was applied to the purpose of furnishing a clock for the famous clock-house near Westminster Hall. In the reign of Henry VI., the king gave the keeping of this clock to William Warby, dean of St. Stephen's, together with 6*d.* per day to be received at the exchequer. St. Mary's at Oxford was furnished with a clock in 1523, out of fines imposed on the students of the university. The middle of the 14th century seems to be the time which affords the first certain evidence of the existence of what would be now called a clock, or regulated horological machine. The first clock at Bologna was fixed up in 1356. Henry de Wyck, a German artist, placed a clock in the tower of the palace of Charles V. about the year 1364. Mention is made in Rymer's 'Fœdera,' of protection being given by Edward III. to three Dutch horologers who were invited from Delft into England in the year 1368. Conradus Dasypodius gives an account of a clock erected at Strasburg about 1370. According to Froissart, Courtray had a clock about the same period, which was taken away by the Duke of Burgundy in 1382. Lehmann informs us that there was a clock at Spire in 1395. Nürnberg had a clock in the year 1462; Auxerre had one in 1483, and Venice in 1497. It appears, from a letter written by Ambrosius Camaldulensis (lib. xv. epis. 4) to Nicolaus of Florence, that clocks were not very uncommon in private families on the Continent about the end of the 15th century; and there is good reason for supposing that they began to become general in England about the same period. The conclusion to be drawn from the evidence here adduced is, that a regulated horological machine is neither of so ancient a date as some writers suppose, nor yet the more recent invention of the last two centuries; and that the inventor is not certainly known. Ferdinand Berthoud was of opinion that a clock, such as that of Henry de Wyck, is not the invention of one man, but a compound of successive inventions, each worthy of a separate contriver. This supposition is confirmed by analogy; for the clocks and watches of the present day have been brought to their present degree of perfection by a series of successive inventions and improvements upon what may now be called the rude clock of De Wyck, the most ancient clock of which we have a description. De Wyck's clock was regulated by a balance in the following manner (*fig.* 1):—The teeth of the crown-wheel E act on two small levers F G, called pallets, which project from and form part of an upright staff or spindle C D, on which is fixed the balance A B; and the mode of adjusting the clock to time was by shifting the two weights W W nearer to or farther from the centre.

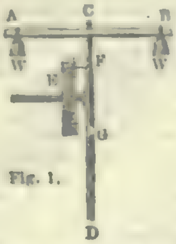


Fig. 1.

Although this clock of De Wyck's, and indeed all those made with a balance for the regulator, without any regulation spring, must have been very imperfect machines, we find that so early as 1484 Walther, and after him the landgrave of Hesse, made use of a balance-clock for astronomical observations. Such, indeed, seems to have been the comparative utility of the clock thus early for astronomical purposes, that Gemma Frisius proposed the use of a portable one for ascertaining the longitude at sea about the year 1530. In 1560 Tycho Brahé possessed four clocks, which indicated hours, minutes, and seconds; the largest had but three wheels, the diameter of one of them being 3 feet, and containing 1200 teeth, a proof of the imperfect state of clock-work at that period. Tycho also observed irregularities in his clocks dependent upon changes in the atmosphere, but does not appear to have been aware how they were produced. In 1577 Moestlin had a clock which made 2528 beats in an hour, and by counting the number of beats made during the time of the sun's passage over a meridian, the sun's diameter was determined to be 34′ 13″. At what time the size of clocks was reduced to a state of portability is uncertain, but it must have been prior to 1544; for in that year the corporation of master clock-makers at Paris obtained from Francis I. a statute in their favour, forbidding any one who was not an admitted master to make clocks, watches, or alarms, *large* or *small*. Before portable clocks could be made, the substitution of the main-spring for a weight, as the moving power, must have taken place; and this may be considered a second era in horology, from which may be dated the application of the fusee; for these inventions completely altered the form and principles of horological machines.

Such was the state of clock-work when Galileo observed that heavy bodies, suspended by strings of the same length, made their vibrations, whether in long or short arcs, in very nearly, if not exactly, the same spaces of time. Although he never applied the pendulum as a regulator to supersede the balance in clocks, yet his discovery was the prelude to a third era in clock-work, namely, the origin of the pendulum clock. The honour of first applying the pendulum to a clock has been a matter of much contention. Huyghens, whether the inventor or not, undoubtedly applied it in the more masterly and scientific manner, and hence has generally been considered the inventor; but it is now known that a London artist, named Richard Harris, invented and made a long-pendulum clock in 1641. Very soon after the application of the pendulum to clocks, the idea of Gemma Frisius was attempted to be realised by the ingenious Huyghens in the construction of a marine clock. He also discovered that its pendulum vibrated slower as it approached the equator, which has led the way to a subsequent discovery that the earth is not a globe, but an oblate spheroid. In 1676, Barlow, a London clockmaker, invented the repeating mechanism by which the hour last struck may be known by pulling a string. Several artists followed in the same line, particularly Quare, Julien le Roy, Collier, Largay, and Thiout. Clocks were soon after this made to show not only mean but apparent time. The principal artists employed in this more curious than useful part of horology were Sully, Father Alexander, Le Bon, Le Roy, Kriegseissen, Enderlin, L'Admiraud, Passement, Rivar, and Graham. The anchor escapement was the work of Clement, a London clockmaker, in 1680. This change in the escapement introduced the practice of suspending the pendulum by a thin and flexible spring. The seconds' pendulum, with this escapement, was called the *royal* pendulum.

Another era in the history of clock-work commenced with the beginning of the 18th century. In 1715 George Graham sought for a means of rectifying the errors of the pendulum, caused by the contraction and expansion of metals under changes of temperature; and this means he found in the celebrated *mercurial pendulum*. John Harrison improved on Graham's arrangement of the pendulum; and Graham himself afterwards introduced his *dead-beat escapement*, as an improvement on the anchor or recoil escapement previously in use. From the days of Graham and Harrison successive improvements have been introduced in every part of the art. Such of those as are of primary importance will be noticed as we proceed.

Chronometers.—A chronometer, an eight-day spring clock, a time-piece, and a pocket watch have this in common,—that their source of power is derived from a coiled spring, and not from a pendulum. Chronometers are in extensive use for determining the longitude at sea, and for other purposes where an accurate measure of time is required, combined with great portability in the instrument. The general appearance of what is termed a pocket chronometer is that of a common watch; and it is generally made to go the same time with once winding up—namely, thirty hours. Those used for nautical purposes are larger, having dial-plates from three to four inches in diameter, and are usually made to go from two to eight days between the times of winding up; they have, in addition to the hour, minute, and second circles, one on which a hand denotes the time in days that the piece has been going since the last winding up. Each chronometer is well secured in a brass box, mounted on gimbals, in order that the machine may preserve one uniform position, and is inclosed in a mahogany case.

A chronometer has for its moving power a main-spring, the variable force of which is equalised or rendered uniform by the introduction of the *fusee*, a very beautiful contrivance. This fusee is a variable lever, upon which the main-spring acts through the medium of the chain. It is a mathematical curve which has this peculiar property, that as the chain winds upon it, the distance from the centre of motion of the fusee to the semidiameter of the chain which is in contact with it continually varies. The variation is in this proportion,—namely, that the distance from the centre of motion of the fusee to the semidiameter of the chain at that point where it leaves the fusee for the barrel, multiplied by the force of the main-spring acting on the chain at that time, shall be a constant quantity; that is, shall be the same whatever point of the fusee may be taken. Thus, at any given distance from the centre of motion of the fusee, its power to turn any machinery is uniformly the same; and as the great or main wheel, which communicates motion to all the rest, is attached to the fusee, their centres of motion coinciding with each other, it follows that the power at the teeth of the main wheel is perfectly uniform: this power is transmitted through the medium of a train of wheels and pinions till it comes to the escapement.

A chronometer differs from a common watch in the escapement, and in having a compensation for heat and cold. The peculiar mode of effecting this compensation consists in having what is technically termed an *expansion balance*. The *figs.* 2 and 3 represent each a balance,—some being made with weights, W W, as in *fig.* 2; others with screws, as in *fig.* 3. Each consists mainly of two segments, and each segment is of steel on the concave side and of brass on the convex; a steel bar, A B, unites them. When such an apparatus is in use, any increase of temperature diminishes the elastic force of the balance-spring, which would cause the machine to lose; but the same degree of heat expands the outer rim of the balance, which is brass, more than it does the inner one, which is steel. Not being able to separate, a curvature of the whole arm takes place, which carries the weight W towards the centre, whereby the inertia of the balance is so much lessened as to allow the balance-spring to exert the same influence as it had previous to the change of temperature. Again, a diminution of temperature increases the elasticity of the spring, which would cause the machine to gain; but the brass contracting more than the steel, produces a curvature of the arm outwards, which increases the inertia of the balance, and allows the spring no more influence over it than it had previous to the change of temperature. The proper situations of the weights W W are found by experiments on the rate of the machine. It is evident that the nearer the weights are to the moveable ends *a a* of the arms, the greater will be the space through which they move by any change of temperature, and consequently the greater the variation in the inertia of the balance; whence, if an increase of temperature causes the machine to lose, or a decrease of temperature causes it to gain, it shows the compensation not to be sufficiently active. In adjusting those balances made with screws, it will readily be perceived that the moving in or out the screws 4 4 will produce a greater effect than 3 3, and these again greater than 2 2, and so on; and, also, that in the adjustment two opposite screws must always be moved in or out the same quantity. The mean-time screws C C can produce no effect on the compensation, as no motion is given to them by the curvature of the arms. It has been found by experiment, that in every balance-spring of sufficient length, there is a part of it which will be isochronal, or nearly so; and this length

Fig. 2.

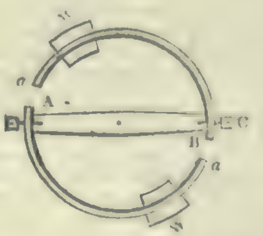

Fig. 3.

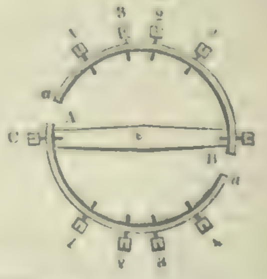


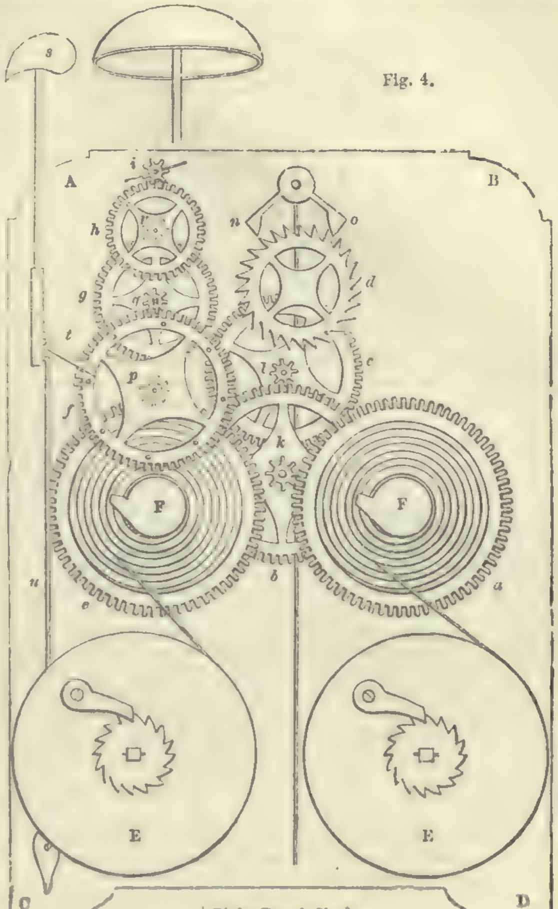
being found, it is not desirable to alter it in bringing the machine to time. To effect an adjustment, the two screws C C have been introduced, the drawing out of which from the centre causes the machine to lose, and the screwing them in to gain.

Many important matters relating to chronometers apply in a smaller degree to spring clocks and to pocket-watches, and will receive notice as we go on. But it is necessary here to say a few words concerning the *competitive trials* of chronometers, which have partly resulted from, and have partly suggested the beautiful inventions perfected within the last few years by Eiffe, Frodsham, Loseby, Dent, and others. Between the years 1822 and 1835, the Admiralty gave rewards as prizes for the good performance of individual chronometers: two or three sums being given annually to the makers of those which showed the smallest amount of error. Nothing was given for any new *principle;* but the general construction was improved by this competition. The relative order of merit was arrived at by taking the number of seconds in the greatest difference between one week's indications and the next, and adding to it twice the greatest difference between one week's rate and the next; the sum was the *trial number;* and that chronometer gained the prize which exhibited the *smallest* trial number. The trials were conducted at Greenwich Observatory, under the Astronomer Royal. After the year 1835 the prizes were withdrawn; but the makers were equally ready to compete, on the score of reputation and commercial advantage. The test was rendered more severe; for every chronometer was exposed in the open air to the fiercest cold of winter; and at other times to the air of a chamber heated to 100° Fahr. In successive years different makers obtained the post of honour; for instance Poole in 1845, Hutton in 1846, Frodsham in 1847, Hewett in 1848, Eiffe in 1849. In the five years here indicated, 219 chronometers were tested at Greenwich; of which 79 were bought for public use, at a maximum price of 62*l*. During the course of these refined experiments, a fact was observed which amounts almost to a new discovery. However perfect may be the compensation of a chronometer for certain temperatures, it was found that it did not remain constant for *all* temperatures. If a chronometer be planned to resist great cold and great heat, it *gains* at medium temperatures; but if specially adapted for the latter, it errs slightly in very cold and very hot weather. The late Mr. Dent explained this fact by supposing that the inertia of a spring balance, as usually constructed, cannot be made to vary uniformly according to temperature, but will vary more rapidly in cold weather than in hot. Chronometer-makers at once set about devising a remedy; and this remedy, however produced, is called the *secondary compensation.* Loseby, Dent, Eiffe, Molyneux, and other makers, have invented highly-curious arrangements of spring balance, all of which have been severely tested at Greenwich, and some of them rewarded by government grants. Loseby's arrangement, which received high commendation from the Astronomer Royal, may be thus briefly described. Attached to the balance is a curved tube containing mercury. The mercury, on expanding with an increase of temperature, arrives at certain parts of the tube inclined in different degrees to the radii of the balance; and therefore its successive expansions produce successive effects of different magnitudes on the momentum of the balance. By giving different forms to the tube, the law of the successive alteration of the momentum may be made to adapt itself to the law of alteration of the elasticity of the spring, whatever that law may be.

Spring Clocks.—In describing spring-clocks, we shall at the same time treat of many parts of the mechanism which are applicable likewise to chronometers, but not described in the foregoing paragraphs.

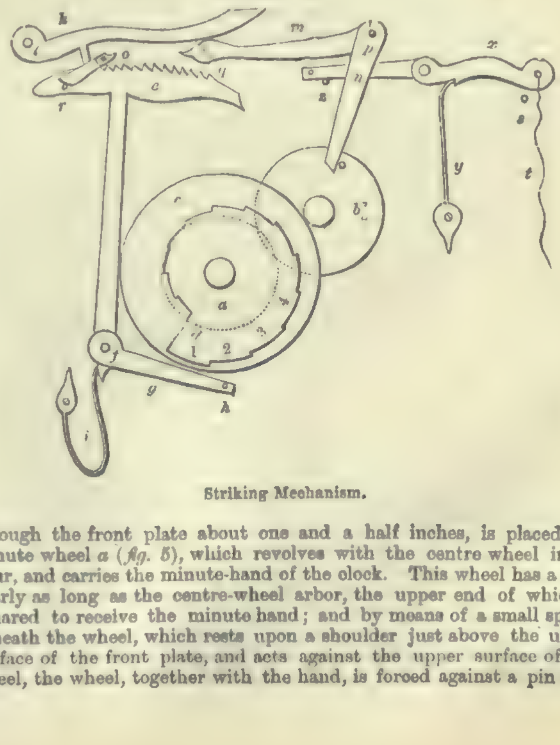
In *fig.* 4, A B C D may be taken as representing the front plate of an eight-day spring clock (which is supposed to be transparent), and is attached to another plate of similar form by five strong pillars between which the wheels here shown are placed. E E are two barrels containing springs; the one on the right gives motion to the train of wheels called the *going* or *watch* train; the other to the *striking* train of wheels *e*, *f*, *g*, *h*, and fly *i*. In producing the series of movements, *a* is the main wheel of 96 teeth, acting in the centre wheel-pinion *k* of eight leaves, to which is attached the centre wheel *b;* this revolves in an hour, and acts in the third wheel-pinion *l*, on which is fixed the third wheel *c*, acting in the swing or scape wheel-pinion *m* (not seen in the cut); to this pinion is fixed the swing-wheel *d*, whose teeth act alternately on the two pallets *n o*, and thereby give motion to the pendulum by means of a piece attached to the arbor of the pallets, one end of which enters a slit made in the pendulum for its reception. F F are the two fusees, the use of which has already been described in connection with chronometers. The method in which the fusees are attached to their respective wheels *a* and *e* is shown in *fig.* 6, where is the main wheel of 96 teeth hollowed out to receive the click *b* and its spring *c* which are attached to the wheel, the ratchet *d* being attached to the under side of the fusee by two screws. In *fig.* 4, *e* is the striking main wheel, having 84 teeth; this drives the pinion *p* of eight leaves, on which is the pin-wheel *f* of 64 teeth, into the rim of which are put eight pins to lift the hammer *s*, by acting upon its tail *t*. The pin-wheel *f* drives the pallet pinion *q* of eight leaves, on which is fixed the pallet-wheel *g* of 56 teeth; this pallet wheel acts in the warning wheel-pinion *r* of seven leaves, on which is the warning-wheel *h* of 48 or 50 teeth, acting in the fly pinion *i*. When in action a pin in the pin-wheel catches the tail of the hammer *t*, and raising it, the hammer-head *s* recedes from the bell; and as soon as the pin leaves the tail of the hammer, the force of the spring *u* acting on the lower part of the hammer produces a blow on the bell. The number of strokes on the bell is regulated by mechanism placed on the outside of the front plate of the clock, but is removed from the figure just described, to prevent confusion. (See *fig.* 5.) On the centre wheel-pinion *k* (*fig.* 4), whose arbor comes through the front plate about one and a half inches, is placed the minute wheel *a* (*fig.* 5), which revolves with the centre wheel in an hour, and carries the minute-hand of the clock. This wheel has a pipe nearly as long as the centre-wheel arbor, the upper end of which is squared to receive the minute hand; and by means of a small spring beneath the wheel, which rests upon a shoulder just above the upper surface of the front plate, and acts against the upper surface of the wheel, the wheel, together with the hand, is forced against a pin over

Fig. 4.



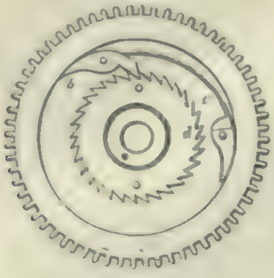
Eight-Days' Clock.

Fig. 5.



Striking Mechanism.

Fig. 6.

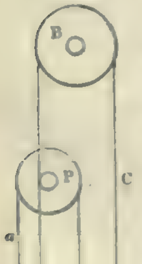


Fusee-wheel.

the hand. The whole of the wheels in this group can therefore be turned forwards or backwards without disturbing the internal mechanism of the clock, or rather that part of it which is called the *going* or *watch* train; for the minute-wheel *a* gives motion to another minute-wheel *b*, which, as it must revolve also in an hour, has the same number of teeth as *a*. A pinion in the centre of the wheel *b* has six leaves, and acts in the hour-wheel *c* of 72 teeth, which is placed over the minute-wheel *a*, and consequently revolves once in 12 hours, and has screwed to its socket, at the upper end, the hour-hand. To the socket of the hour-wheel, about one-eighth of an inch above the wheel, is fixed a piece in which are 12 steps, each of which includes an angle of 30°, or a twelfth part of a circle; this piece is called the *snail*, and is represented by *d*. *e* is a rack whose centre of motion is a stud or pin *f*, on which it acts by means of a pipe about half an inch long, and on to the upper end of which is riveted the rack-tail *g*; in this rack-tail is a short pin *h*, pointing perpendicularly downwards to the front plate of the clock. The rack lies about the tenth of an inch above the front plate; but the pipe which acts on the stud is long enough to carry the rack-tail just clear of the snail when the rack is forced back by the spring *i*; whilst the pin *h* is long enough to strike against the steps in the snail, and yet so short as to be perfectly free of the hour-wheel *c*. Near this is *k*, the rack-hook moving freely on a stud; *m* the lifting piece, also moving freely on a stud *p*; *n* the tail of the lifting-piece firmly pinned on to the upper part, and moving with it; *o* the gathering pallet, which has a square hole through it, and is fixed upon the square end of the arbor *q* of the wheel *g* (*fig.* 4) which revolves once for every blow given by the hammer. A pin in the warning-wheel *h* always stands in the same position when the striking part is at rest, which is the position represented in *fig.* 4. On the end of the lifting-piece is a small piece *q* (*fig.* 5), which passes through a slit in the front plate, and resting on the bottom of the slit, keeps the lifting piece in its proper position. The gathering pallet *o* rests on a pin *r* in the rack, and thereby prevents any motion in the internal wheel-work of the striking train. Such being the mechanism, the mode of action will be understood from a study of the figures, without a detailed description. A small piece *x* is called the *pull-piece*, by pulling a string at the end of which the lifting-piece is raised, and the clock is made to repeat the hour last struck at any required time. *y* is a spring to force the pull-piece *x* against the pin *z* fixed in the plate of the clock; *s* is another pin to limit the motion given to the pull-piece *x* when the string *t* is pulled.

Pocket-watches.—Without attempting to notice the numerous improvements in spring clocks, we shall proceed briefly to describe those features in a pocket watch which are of a distinctive character.

Fig. 7.



Endless Cord.

When clocks and watches had acquired a certain degree of accuracy in their performance, the time lost in winding up (especially when it had to be done every twenty-four hours) became a matter of importance; and there have been several inventions to remedy this evil, by producing what is called a *maintaining power*. By Huyghens the clock was kept going while winding by means of an *endless cord*, as in *fig.* 7. B is the clock-barrel; C, that portion of the line which comes from the barrel to the weight; P, a pulley for the line to run over; Q, a pulley for the line to run under, and to which is attached a small weight *w*. It will be seen by inspection that the hand applied to that part of the line marked *a* will be able to raise the weight W without depriving the barrel B of any portion of the power by which it is urged forward, and which power in this arrangement is equal to one-half of the weight W. Another kind of maintaining power is the *forcing spring*, shown in *fig.* 8. A lever A, whose centre of motion is *o*, has a notch cut in its end, into which is jointed a small lever *c*, whose centre of motion is *x*; this small lever is kept in its proper position against the bottom of the notch, as shown in A, and also in B (which is only another position of the lever), by a slight spring *s*. D is a strong spring which acts constantly on the lever A, having a tendency to force it into the position represented by B, in which it is not in action. Previous to winding the clock up, the end E of the lever is depressed and brought from position B to that of A; and in its progress in passing a tooth of the wheel the small lever *c* assumes the position represented in *fig.* 9, which it is allowed to do by the very slender spring *s*. As soon as the tooth is passed, the pressure of *s* obliges the lever *c* to return to its original place; and by the pressure of its opposite end on the bottom of the notch in which it is inserted, the lever A is prevented from regaining its former position by the pressure of the piece *c* on the tooth of the wheel—until the wheel shall have advanced so far as to have allowed its escape, when the lever regains its position B, where it remains till another winding becomes necessary. It will be evident that so long as *c* remains on a tooth, the wheel will be urged forward by the action of the spring D. *e e* are two pins which are fixed in the plate of the clock, and serve to determine the quantity of motion given to the lever A.

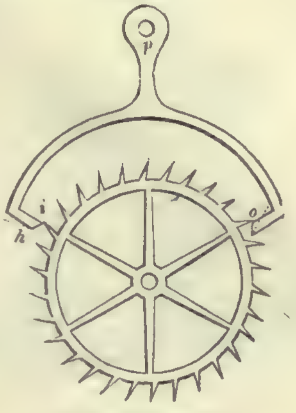
Harrison's Maintaining Power—Going Fusee.

1, Fusee auxiliary ratchet, and fusee-wheel attached; 2, fusee-wheel and auxiliary spring, separate; 3, 4, upper and under sides of the fusee, separate; 5, auxiliary ratchet *q*, with clicks *a a*, and springs *e e*, attached.

Harrison's contrivance for the same purpose, however, is the one now in general use, both in clocks and watches, and is admirably adapted to the purpose. When this principle is applied to a fusee, it is termed a *going fusee*; but *maintaining power*, as a more comprehensive term, is now generally applied. Into the hollow of the fusee-wheel is placed a circular spring *a b c*, (*Fig.* 10), which is secured to the wheel by a pin at about one fourth of its circumference from the end *a*, namely, at *b*. The wheel has a short notch cut through it, near the other end of the spring. The spring passes over this notch; and by means of a pin *c*, fixed firmly in the spring and projecting through the notch in the wheel, a motion is allowed to the spring, which in extent is equal to the difference between the length of the notch in the wheel and the thickness of the pin which passes through it. It is the reaction of this spring through the short distance already mentioned which maintains the motion in the watch during the time of winding up. Instead of any click and spring being attached to this fusee-wheel, as in an ordinary eight days' clock, there is a circular disc of steel, rather larger than the bottom of the fusee, and smaller than the fusee-wheel, having very fine ratchet-teeth cut in its edge, and two clicks *a a* and springs *e e* on its upper surface, in which the ratchet fixed on the under side of the fusee, and called the fusee-ratchet, acts. The steel-ratchet is called the auxiliary-ratchet, and its teeth stand in a direction opposed to those of the fusee ratchet. We will now suppose the auxiliary ratchet to be laid on to the fusee-wheel over the spring *a b c*; a hole in its centre passing over a short pipe in the centre of the fusee-wheel retaining it in its situation; the pin *c*, which we have described as projecting through the notch in the fusee-wheel, also projecting upwards just equal to the thickness of the auxiliary-ratchet, through which it likewise passes; and the pin exactly fitting the hole in the ratchet. In this situation the wheel and ratchet are ready to receive the fusee with its ratchet; but it must be borne in mind, that though the pin *c* fits exactly in the hole in the auxiliary-ratchet, and thereby prevents it from turning round, it does not prevent its having as much motion as the spring itself has in the notch in the fusee-wheel; the spring must also be conceived to have been forced into its place with the pin pressing strongly against the end of the notch *o*. The fusee is now attached to the wheel by passing its arbor through the hole in the centre of the wheel, and is secured in its place by a pin and collet on the opposite side, which prevent their separation, at the same time allowing the fusee to turn with a moderate degree of force. In this state the fusee, &c., must be considered as placed within the frames of the clock or watch in connection with the other part of the train of wheels, &c. A click, or, as it is sometimes called, a detent, is also placed between the frames, and by means of a slight spring is made to act in the teeth of the auxiliary-ratchet. The action of the whole apparatus will be understood by comparing the relative positions of the several parts. The space through which the spring *a b c* acts in the notch *o p* with sufficient force to maintain the motion of the watch, is about equal to two teeth of the fusee-wheel; and the time in which the fusee-wheel goes through a distance equal to two teeth varies in different watches from 10 to 12 minutes, a time more than sufficient for the operation of winding.

We must next describe the *escapement*, so important in horology. This term is applied to a combination of parts in a clock or watch, which has for its object the conversion of the circular motion of the wheels into a vibratory motion, as exhibited in the pendulum. In the description we are about to give, the term will be made to include the scape-wheel, the pallets with their arbor or axis, and a bent lever attached thereto, called the crutch, which last piece maintains the motion of the pendulum. In a watch this combination consists of the scape-wheel, together with all those parts lying between it and the balance, and which are concerned in converting the circular motion of the wheels into the alternating one of the balance. In Graham's *dead-beat escapement* the distance between the centre of motion *p* of the pallets and the centre of the scape-wheel is equal to one diameter of the scape-wheel. In *fig.* 11, the tooth *i* has just given impulse to the pallet P and escaped from it; the tooth *o* has in consequence fallen upon that part of the pallet Q called its arc of rest, which, in both pallets, is formed by a circle struck from the centre of motion *p* of the pallets. The impulse given by *i* causes the pendulum, and with it the pallets, to vibrate some distance after *i* has left P and *o* has fallen on Q; but the arc of rest being concentric with the centre of motion of the pallets, the wheel ceases to rotate, or remains *dead*, until the pendulum by its returning vibration lifts the pallet Q so high as to allow the tooth *o* to get upon the face or inclined plane of the pallet, upon which it then acts. The tooth drives up the pallet, and with it the pendulum, until the tooth *o* escapes from the pallet Q; when another tooth *h*, on the opposite side of the wheel, falls on the arc of rest of the pallet P, which arc is in this pallet on the outside, and on which the tooth rests until by the return of the pendulum the pallet P is lifted so high as to allow *h* to get on the inclined plane or face of the pallet P, upon which it acts. The tooth raises the pallet and with it the pendulum, till it escapes and gains the position *i*, when the same process is repeated: the wheel alternately giving impulse to one pallet and resting on the circular part of the other, which we have denominated the arc of rest. When the pendulum is in a state of rest, some one tooth is always resting on one of the circular arcs; the pendulum being put in motion brings a pallet into a position to receive an impulse from the wheel-tooth, when the process already described commences.

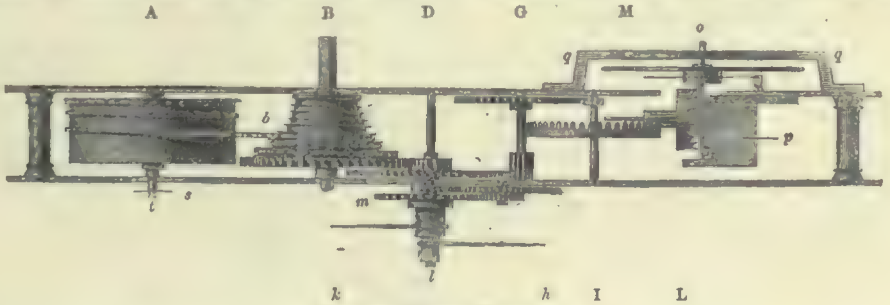
Fig. 11.



Dead-Beat Escapement.

Most of the great improvements in pocket watches have been made in the *horizontal* or *flat* forms; but the common *vertical* watch must be first described.

Fig. 12.



Section of Vertical Watch.

The annexed cut (*fig.* 12) represents such a watch as it would appear if the dial (which is here omitted) were turned downwards. A is the barrel; B, the fusee; *b*, the chain by which motion is communicated from the barrel to the fusee, on which is the great or fusee wheel acting on the centre-wheel pinion D, on which is riveted the centre-wheel: the arbor of the pinion D being prolonged through the plate of the watch as far as *l*. The centre-wheel and its pinion revolve in an hour. Upon that part of the arbor D which is on the outside of the plate or frame is placed the cannon-pinion, which has a hole quite through it for the reception of the centre-wheel arbor, on which it turns spring-tight. The cannon-pinion is secured in its place by a small pin through the end of the centre-wheel arbor *l*, the end of the pinion being squared to receive the minute-hand *h*. The cannon-pinion has 12 leaves acting in the minute-wheel, of 48 teeth, causing the latter to revolve once in four hours. Concentric with the minute-wheel, and attached to it, is a pinion, having a hole through their common centre, through which passes a stud fixed on the plate. This pinion, having 14 leaves, drives the hour-wheel *m*, of 42 teeth, once round in 12 hours; this wheel is placed over the cannon-pinion by a socket, which has a hole through it for the cannon-pinion to pass through; on this socket is fixed the hour-hand *k*. It will be perceived that by this arrangement the cannon-pinion, minute-wheel, pinion, and hour-wheel, together with the hands, can all be turned backward or forward without affecting the interior mechanism of the watch, simply by the application of a key to the squared end of the cannon-pinion. The assemblage of wheels, &c., thus put in motion is called the *motion-work* of the watch; that between the plates, the *movement*, which we shall next describe. The centre-wheel gives motion to the third wheel-pinion, to which is attached the third wheel G, acting upon the contrate-wheel pinion. On this is placed the contrate-wheel acting in the pinion of the balance-wheel L, which is also called the scape-wheel. We have already explained the mode by which the balance-wheel teeth act upon the pallets, so as to cause an alternating motion in the balance M. One end of the balance-wheel arbor works in a piece called the dovetail, which is inserted in a piece *p*, called the potence, firmly attached by a screw to one of the plates of the watch; the other end works in a piece called the follower, which is inserted in another piece riveted into the plate called the counter-potence, (left out of the figure to prevent confusion). Another part of the potence, called the foot, receives one end of the balance arbor or spindle, called the verge (on which are the pallets); the other end works in a hole in the pin *o*, which passes through the centre of the cock *q q*, which is secured to the upper plate of the watch; the pendulum-spring (also called the regulating-spring and hair-spring) has one end, immediately below the balance, secured to a stud fixed in the plate, and the other pinned fast to a small collet, which goes spring-tight unto the axis of the verge, and is seen just under the balance. *Figs.* 13, 14, and 15, represent some of the parts separately. *Fig.* 13 shows the main-spring in a relaxed state as it would appear out of the barrel; to which, when in, one end of it is attached, the other being held by a hook in the arbor of the barrel, which comes through the plate, as shown in *fig.* 12, and is kept from turning by a ratchet and click. The spring is wound up by the chain acting on the barrel and pulling it round, which operation is performed by turning a key placed on the squared end of the fusee-arbor. The effort of the spring to unbend itself after being wound up causes the barrel to revolve in a contrary direction to that in which it moved whilst winding up, and thereby gives motion to the fusee, and with it the fusee-wheel and the rest of the train. *Fig.* 14 represents the barrel and fusee, with the chain attached. *Fig.* 15 shows the balance-wheel, balance, and verge, with the hair-spring attached to it.

Fig. 13.

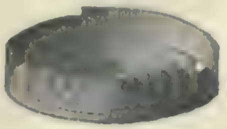


Fig. 14.

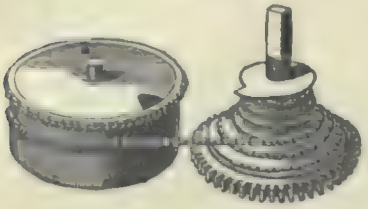

Fig. 15.

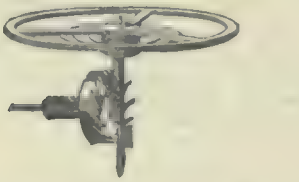
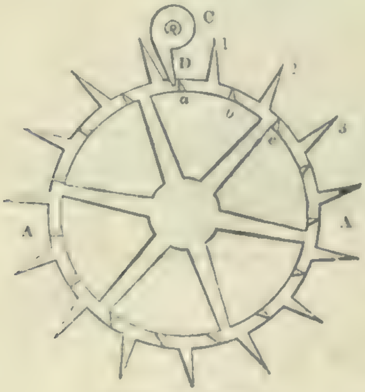


Details of Vertical Watch.

We shall now notice the better kinds of watches, the peculiarities of which mainly depend on the escapement.

The *Duplex Escapement* is shown in *fig.* 16. A A is the scape-wheel, 1, 2, 3, being the teeth of repose, and *a*, *b*, *c* the teeth of impulse, which are triangular, and stand perpendicular to the plane or surface the wheel. C D, the impulse pallet, fixed upon the arbor of the balance, and standing just above the surface of the wheel A A, receives its motion from the teeth *a*, *b*, *c*, &c. After the tooth *a* has passed the pallet C D, the tooth *b* comes in contact with a small roller made of ruby, and placed on the lower part of the axis of the balance, where it remains till the balance is brought back by the balance-spring to such a position that the notch, shown by the dotted line in the ruby roller, will allow the tooth 1 to enter it, and thereby pass the balance-arbor, or escape, which it does by the wheel A A being constantly urged in the direction from 3 to 1. As soon as tooth 1 escapes from the notch, tooth *b* gives a fresh impulse to the pallet C D, and the act of escapement is thus repeated; the wheel moving forward one whole tooth, and the balance making two vibrations for each impulse given by the upright teeth.

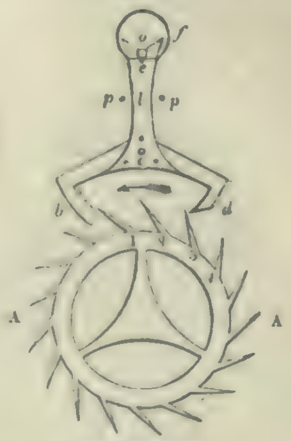
Fig. 16.



Duplex Escapement.

Another effective variety, the *lever escapement*, is shown in *fig.* 17. The lever *l* is placed on the pallets in a position at right angles to that in which it is usually placed in a watch, by which means we think the principle will be more apparent to the general reader. A A is the scape-wheel moving in the direction of the arrow; *b d* the pallets, whose centre of motion is *c*. To the pallets is pinned the lever *l*, in which is the guard pin *e*, pointing upwards from the lever *l*; the roller *f* is fixed on the axis of the balance, and stands just above the lever *l*, having a piece cut off from its circumference to allow the guard pin *e* to pass and repass the roller, which it does when the escape takes place. *o* is a ruby pin fixed in the roller, and pointing downwards through the notch in the end of the lever *l*. When the balance is quiescent, the pin *o* is in the notch in the end of the lever *l*, and the guard-pin *e* in the position shown in the figure, where the tooth 1 acts on the pallet *b*, which causes the balance to vibrate. The guard-pin *e* proceeds a short distance to the right of its present position, and the lever is prevented from returning by the guard-pin *e* coming in contact with the circular edge of the roller. When an impulse is given by a tooth to the other pallet *d*, the lever *l* impels the ruby pin *o* to the left hand, where precisely the same effects take place with regard to the guard-pin *e*, &c., as have been already described. If the pallets *b* and *d* were of the form shown by the dotted lines (which are supposed to be circular arcs concentric to the centre of motion *c* of the pallets), it is evident it would be a perfect dead beat, like the clock escapement previously described; but in order, after the escape has taken place, that the guard-pin *e* may be retained at a small distance from the roller, that part of each pallet on which the tooth rests when it falls on the pallet is taken off, as shown in the figure; and as the faces of the wheel-teeth are considerably undercut, the wheel advances a small distance, after having fallen on that part of either of the pallets which is within the dotted line. This further advance of the wheel draws the pallet down towards the centre of the wheel, and thereby keeps the guard-pin *e* at a slight distance from the edge of the roller *f*. As soon as the balance has performed so much of the returning vibration as to bring the ruby pin *o* into the notch in the lever, the momentum of the balance, acting through the medium of the ruby pin *o* upon the lever, moves it a short distance, and thereby lifts the pallet outwards from the centre of the wheel and unlocks it. During this unlocking the wheel retrogrades (before it can get upon the face of the pallet to give a fresh impulse) just as much as it had previously advanced after falling on the pallet. By this retrograde motion the tooth gains the inclined plane or face of the pallet, and gives a new impulse; and the same process is repeated by another tooth on the opposite pallet. *p p* are two pins, called banking pins, against which the lever *l* presses when locked, and which prevent the guard-pin *e* from being drawn too far away from the edge of the roller *f*, when the locking takes place.

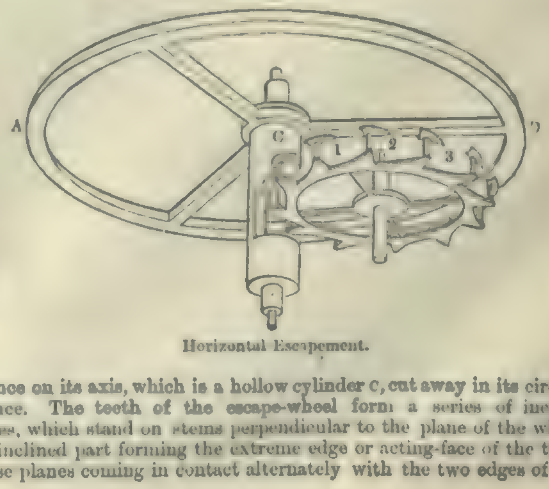
Fig. 17.



Lever Escapement.

In *fig.* 18 is shown a *horizontal escapement*. A B C represents the balance on its axis, which is a hollow cylinder C, cut away in its circumference. The teeth of the escape-wheel form a series of inclined planes, which stand on stems perpendicular to the plane of the wheel; he inclined part forming the extreme edge or acting-face of the tooth. These planes coming in contact alternately with the two edges of that

Fig. 18.

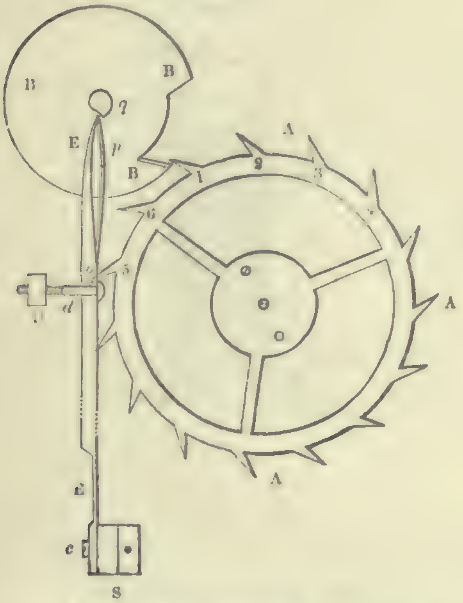


Horizontal Escapement.

part of the cylinder which has the least portion of its circumference taken away, when a tooth is in the cylinder, the point rubs against the internal surface until the balance by its vibration gets into such a situation that the inclined plane can act upon its edge. It then impels the cylinder in the direction from D to A; until the highest part of the plane escapes from the inside of the cylinder, and the next tooth falls upon the outside. This tooth continues to rub until the balance completes its vibration and has returned so far as to permit the point of the tooth, which has been rubbing on the outside of the cylinder, to get upon its edge, where it gives impulse to the cylinder; and when its heel escapes, the point falls on the inside of the cylinder, and the former process is repeated. 1, 2, 3, &c., are teeth of the horizontal or scape-wheel, one of which is seen inside the cylinder; the dotted lines represent the face or inclined plane of the tooth, which is just coming in contact with the edge of the cylinder. The direction of the motion of the wheel is from 1 to 3; the proportion of the cylinder to the wheel is such, that a tooth of the wheel, when in the cylinder, may just have sensible shake; and the outside diameter must be sensibly less than the distance between two teeth.

The *detached escapement*, such as is used in a modern chronometer, is shown in *fig.* 19. A A A is the scape-wheel, made either of brass or steel, the teeth 1, 2, 3, 4, &c., of which are considerably undercut on the face. The steel-roller or main-pallet B B B, which is fixed on the arbor of the balance, has an opening in it, the face of which is also much undercut as shown near B, and has set in it a piece of hard stone, such as a ruby, for the points of the teeth to act upon. S is a stud firmly fixed to one of the plates to which the detent-spring E E is secured by a screw *c*. This spring is made extremely slender and weak in the part E near the stud; and it is only by the yielding of this thin part of the detent-spring that any motion can be given to the detent for the purpose of unlocking the wheel; so that some part of this spring may be considered as the centre of motion of the detent. D is a stud also fixed to the plate of the watch, into which is inserted a screw *d*, against the head of which the detent rests. *o* is a ruby pin inserted in the detent, pointing downwards from the detent; so that one of the teeth of the wheel which is supposed to pass under the detent may rest on the pin; and in this state the wheel is said to be locked. To the inner side of the detent is attached a very delicate spring, called the lifting-spring, which rests upon and extends a little beyond the end of the detent. Concentric with the main pallet, and just above it, is a small lifting-pallet *q*, which should be flat on its face or lifting-side, and rounded off on the other side. In the position given in the figure, the lifting-pallet *q* is just coming with its face in contact with the lifting-spring *p*; which in the course of vibration it lifts, and with it the detent (on whose point the lifting-spring presses), so as to raise the pin *o* clear of the wheel-tooth 5. By the time the wheel is free from the ruby-pin, the main-pallet has advanced so far as to be ready to receive an impulse from the tooth 1; and before the tooth escapes the lifting-pallet *q*, parts with the spring *p*, and the detent resumes its place on the head of the screw *d*. In this position the ruby-pin receives the point of tooth 6, as soon as tooth 1 has escaped from the ruby-face of the main-pallet B B B. The balance, having performed this vibration by the impulse given to the main-pallet, returns by the force of the balance-spring, and with it the lifting-pallet *q*. The rounded side of the latter pressing against the lifting-spring *p*, raises it from the detent, and passes without disturbing the detent, which is not again lifted till the balance has completed the present vibration, and returning for the next. In so doing it again brings the face of the lifting-pallet in contact with the lifting-spring, which (with the detent) it raises, and the act of escaping again takes place; the balance making two vibrations for every impulse, as in the duplex. This escapement, which was invented by Earnshaw, is one of the best for simplicity and for performance.

Fig. 19.



Detached Escapement.

The name *repeating-watch*, or *repeater*, is applied to a watch which, in addition to showing the time on a dial, is supplied with mechanism by putting which in action the wearer is enabled to ascertain the time within certain limits. We have shown, in describing an eight-day clock, how the number of blows given by the hammer to the bell is made to correspond with the hour denoted by the hands of the dial; and also that, by pulling a string, the clock will at any time repeat the hour last struck. But this will not be the case where the minute hand has approached within about ten minutes of twelve o'clock, for from that time till the hand comes to twelve the clock is *on the warning*, and is in such a position that it cannot strike at all. This defect is remedied in *repeaters*. Most repeaters are watches which are capable of striking on a bell or spring the hours and quarters; but there are others which also strike the minutes, and these by way of distinction are called *minute repeaters*. In a repeater, besides the going-train and the motion-work, there is an additional train of wheels between the frame-plates, called the *runners* or *little* wheel-work, or sometimes the *repeating-train*. This train serves the purpose of regulating the rapidity with which the successive blows shall be given to the bell, and consists generally of five wheels and five pinions. The last pinion in the train, performing the office of a fly-wheel, is generally called the fly-pinion; and, when the striking is regulated to its ordinary rate, makes about two hundred revolutions to every blow of the hammer. The chief use of these intricate pieces of mechanism is to furnish the means of knowing the hour of the night in the dark.

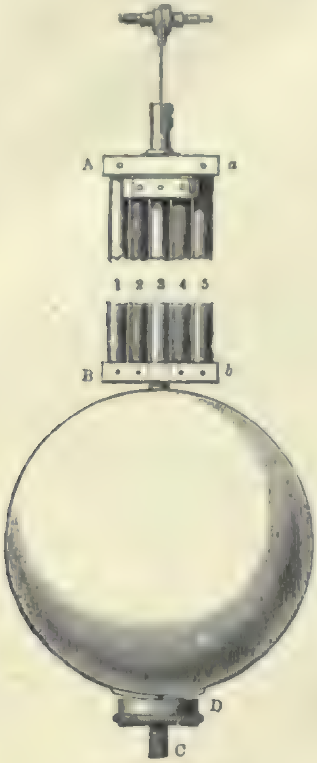
All the more delicate pivots of chronometers, and of the better kind of watches, work in jewelled holes, which will be found described under JEWELLING.

Pendulum Clocks.—We now arrive at the consideration of those horological machines which receive their regulating adjustment by means of the pendulum.

The sensible equality of the oscillations of a weight suspended by a string or wire was first applied as a regulator to a clock by Huyghens about 1657. The successive improvements in the escapement, which sustains the motion of the pendulum and records its vibrations, and those in the pendulum itself, which secure a perfect equality in the duration of each oscillation, have finally produced the astronomical clock, the most accurate machine which man has hitherto constructed, and one of the most essential instruments in a modern observatory. We shall suppose that the dead-beat, or Graham's escapement, is that adopted. The pallets P Q, *fig.* 11, have motion on an arbor which passes through *p*, and has its pivots resting in holes in the clock-frame. A slender bar or wire, called the *crutch*, is attached to this arbor, and a notched piece projecting outwards and backwards from the crutch clasps the rod of the pendulum. The pendulum is hung from a cock at the back of the frame, and moves with the crutch. In a well-made clock, the error arising from expansion from temperature is the most considerable, and is that which must be guarded against. Before explaining more accurate and costly contrivances, it will be well to point out one recommended by Mr. Francis Baily. ('Mem. Astron. Soc.,' vol. i., p. 381.) Take a cylinder of lead about 14 inches long, and pierced through its axis, as a bead, with a hole large enough to admit freely the rod of a wooden pendulum. This hollow cylinder rests on a nut, which works on a screw in the continuation of the rod below. The rod itself, from the centre of motion to the nut, will be about 46·0 inches. As it is easier to cut the cylinder shorter than to lengthen it, and as the expansion of the spring is not allowed for, and that of the wood is somewhat uncertain, it will be better to make the leaden cylinder an inch longer for a first trial; but even if the pendulum should turn out to be *under* compensated, an additional ring of lead may be added, above or below, of the thickness required.

To the best clocks it is usual to apply either the gridiron pendulum of Harrison (which was once chiefly used in England, and is still in repute abroad), or the mercurial pendulum of Graham. The annexed figure (*fig.* 20) is not exactly the pendulum as arranged by Harrison, but accords with his principle. The steel rods 1 and 5 are pinned into two brass cross-pieces, A*a*, B*b*. The zinc rods 2 and 4 are pinned below into B*b*, and carry a cross-piece above, into which the steel rod 3 is pinned. Rod 3 passes freely through a round hole in B*b* (this is shown by dotted lines), and is tapped into a screw below; the bob rests upon the nut, which works on the screw. The steel rods 1 and 5 expand downwards, the zinc rods 2 and 4 expand upwards, and the steel rod 3 downwards; and it is possible so to adjust their lengths (the expansion of zinc being more than double that of steel) that the effects of the expansion downwards and upwards shall have no effect on the length of the pendulum or time of oscillation. Harrison used brass instead of zinc for the upward expansion; and in order to produce a perfect compensation, was forced to use four more rods, a second pair of brass to expand upwards, and another pair of steel to expand downwards: nine in all. The foreign artists use zinc, which requires only five bars, less workmanship, and only one nice fitting. One or two flat brass horizontal bands are attached to 1 and 5 to keep the zinc rods in their places.

Fig. 20.

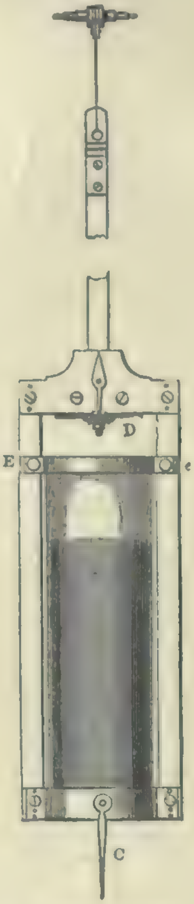


Gridiron Pendulum.

In Graham's pendulum, a glass jar, partly filled with mercury, is supported in a sort of steel stirrup. The pendulum rod passes through the top of the stirrup, and is held by a nut and adjusting screw at D, *fig.* 21. The height of the mercury in the jar is about 6·7 inches; but this will vary somewhat with the diameter of the jar, the substance of the rod and frame, and perhaps the variable expansion of the steel rod. The compensation can be altered, and finally perfected, by the astronomer.

Mr. Dent has recently made many improvements in the mercurial pendulum. One consists in the use of a cast iron instead of glass cistern for the mercury; another in the attachment of the cistern directly to the pendulum-rod; a third, in the prolongation of the rod nearly to the bottom of the cistern; and a fourth, in giving impulse to the pendulum at or nearly at the centre of percussion. If an escapement could be contrived which gave its impulse to the pendulum at the middle point of its vibration, and was wholly *detached* from it at all other times, such an escapement would be perfect; and escapements are almost to be considered good or bad as they approach this character. Huyghens proposed a most ingenious contrivance, namely, that the upper part of the pendulum, which he made of two parallel strings, should wrap and unwrap on two cheeks, which being shaped as cycloids, caused the bob itself to describe a cycloid. Now it is a property of this curve that all arcs are described in the same time, so that Huyghens's construction was perfect in principle; it had, however, many difficulties in practice. Instead of suspending the pendulum by a perfectly flexible string, or on a knife-edge, when the motion must be in a circle, the top of the rod may be made to end in a flat spring, which has certain advantages. Mr. Frodsham has found that a spring of a particular strength rendered the oscillations of a pendulum of a certain weight isochronous, and that a considerable alteration in the length of the spring did not affect this quality of isochronism. This may perhaps be explained by supposing the lower part of the spring not to have acted when it was longest, but to have always preserved its rectilinear form. There is an investigation of the effect of atmospheric pressure on the rate of a transit clock at the Armagh observatory, in the 'Mem. Ast. Soc.,' vol. v., p. 125. The author, Dr. Robinson, assumes that the variations of a clock from a constant rate are expressed by the sum of two terms, one depending on the temperature, the other on the pressure of the atmosphere shown by the barometer. The isochronism of the spring is supposed, or that the effect of any change in the arc depending on the above two causes is already expressed in the terms. When the error in the compensation for temperature is determined, this can readily be rectified by altering the quantity of mercury in the jar. As the effect of time is generally to produce a falling off in the arc, a small addition to the clock weight might be made from time to time, so as to bring back the pendulum to its primitive arc, until the clock is cleaned, and its action restored that way. Where the clock is much exposed to variations of temperature, it should be enclosed in a second covering or closet.

Fig. 21.



Mercurial Pendulum.

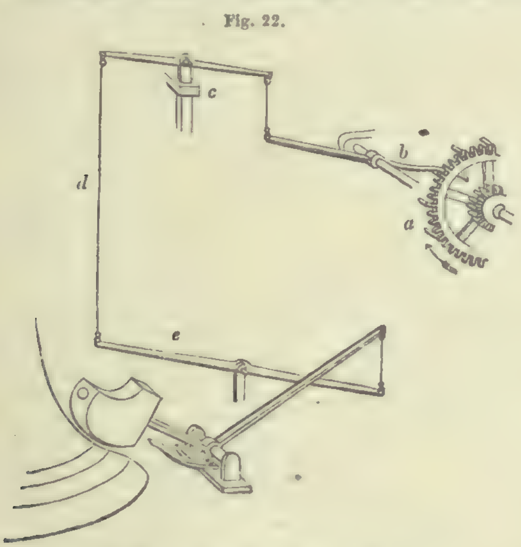
To bring a clock to time, first make it nearly right by the adjusting screw D, but let it have a losing rate, which must be determined by observation after the interval of one or more days. Suppose it is losing 3^s a day. Put a weight, which has been carefully ascertained, say 200 grains, upon the plate which covers the jar (E *e* in the mercurial pendulum, in the gridiron pendulum anywhere near B *b*), and find the fresh rate of the clock by observation. Let it now gain 10^s a day. Then, as 200 grains cause a gain of 13^s a day, 15·4 grains will alter it 1^s per day, and, replacing the 200 grains with a weight of 46·2 grains, will bring the clock to time. The final adjustment of the compensation can be best accomplished when the clock has gone several months, and when the gain or loss in two of the warmest months in the year is compared with the gain or loss in two of the coldest.

For the mathematical and physical principles which govern the action of the pendulum, we refer to PENDULUM.

An *astronomical* clock, such as those used in observatories, is the best example of a pendulum clock, comprising all the most refined means of adjusting the isochronous movements of the pendulum to the measurement of small intervals of time. *Turret* or *church* clocks, however, are commercially of more importance, and of these we must now say something.

Turret-clocks differ from other machines employed for measuring time, not only in their greatly superior size, but also in the arrangement of their parts, and in the circumstance that they are usually make to strike the hours, and often the quarters also, upon large bells. They are also occasionally connected with machinery for chiming whole tunes at certain intervals upon a set of bells which, when mounted in a church tower, are so hung that, by disconnecting the hammers of the chimes and striking apparatus, they may also be rung in the ordinary manner by means of ropes. One of the peculiarities of a turret clock consists in the circumstance that it is frequently required to indicate the time upon as many as four different dials, on the four external faces of the tower in which it is mounted. This apparently difficult matter is accomplished in a simple and beautiful manner: by placing the clock in or near the centre of an apartment either on a level with the external faces, or above or below them, and causing the motion of the minute-hand axis to be transmitted by bevil-gear to a vertical rod, the opposite end of which carries a horizontal bevil-wheel nearly on a level with, and situated centrically with reference to, the four external dials. The motion of this central wheel is communicated by four vertical bevil-wheels of the same size and number of teeth, ranged round its circumference, to four horizontal rods, the opposite ends of which, passing through the several dials, carry the four minute-hands. At the back of each dial is a series of wheels and pinions, constituting the motion-work; while the movement of the hands and that of the striking apparatus are provided for by separate trains of wheel-work, each of which is impelled by its own moving power. In a turret-clock, the moving power is supplied by the descent of a weight, regulated in the case of the movement, or going-train, by the oscillations of a large pendulum, and in that of the striking-train by the resistance of the air to the rapid revolutions of a fly or fan set in motion by the wheel-work. The weights are wound up (in most cases, weekly) by means of winch-handles and toothed wheels connected with the massive drums round which their ropes are coiled; and, for convenience, they do not descend immediately from the drums or barrels, but in the angles of the tower, or any convenient situation, the course of their ropes being directed by guide-pulleys. *Fig.* 22 may serve as an example of the striking mechanism of turret-clocks in general, although the details of course vary according to the relative situation of the clock and the bell, which in some cases is the reverse of that here represented. In this cut, *a* represents the pin-wheel, by the action of the projecting pins of which upon the end of the lever *b*, communicated through the levers *c* and *e*, the tail of the hammer is depressed, and the hammer-head is consequently raised ready for a stroke. By the continued revolution of *a*, the end of the lever *b*, after being raised to a considerable height, is suddenly released, by which the hammer falls upon the rim of the bell, and the connecting apparatus resumes its original position ready for the next stroke.

Fig. 22.

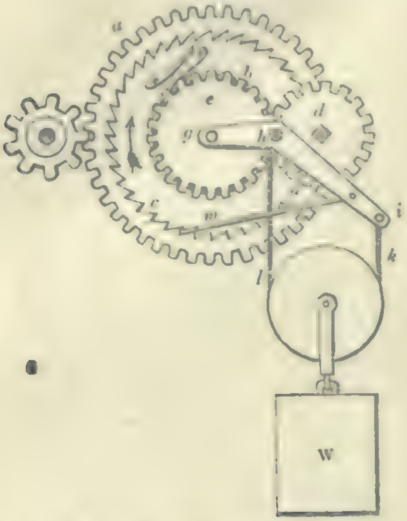


Striking mechanism of Turret-clocks.

Musical chimes, which form a pleasing though not very common addition to the mechanism of turret-clocks, require the addition of another train of mechanism, somewhat like that which constitutes the striking-train; inasmuch as it is perfectly at rest for considerable periods of time, and is brought into action only at certain predetermined intervals by the action of the going-train of the clock upon a detent. The mechanism of the chimes very nearly resembles, on a large scale, that of a musical snuff-box; levers connected with hammers which strike upon a series of bells, being substituted for the springs which in the musical snuff-box are caused to vibrate by the projecting pins on the revolving barrel.

Owing to the very limited demand for turret-clocks, and their great durability when well made and carefully preserved, the business of making them is confined to very few establishments, and has hardly been systematised into a manufacture. Every clock being, in ordinary cases, made individually, and with comparatively little aid from machinery, turret-clocks have been very expensive, and in many cases inferior in accuracy of workmanship to many far simpler, cheaper, and more common machines. The late Mr. Dent, when engaged about the year 1843 by the Gresham Committee to make a turret-clock, of unprecedented perfection, for the new Royal Exchange, under the superintendence of Mr. Airy, the astronomer-royal, determined to meet this deficiency by establishing a clock-factory supplied with all the aids and appliances of modern ingenuity, in which the several parts of a turret-clock should be produced as far as possible in the same way as the component parts of a power-loom or other machine manufactured upon an extensive scale. In the Exchange clock, he adopted the use of a simple but strong cast-iron framing, in which every strain is so completely self-contained, that the operation of fixing the clock in its destined position is one requiring but little skill, scarcely any adjustment being required beyond the fixing of the frame on a firm and level base. Another, and a more unusual feature, which Mr. Dent (borrowing from the French) has introduced into the turret-clock manufacture, although it is not adopted in the Exchange clock, is the use of cast-iron wheels for the striking-train. After many experiments, Mr. Dent came to the conclusion to use for the wheel-teeth (the driver) the epicycloidal curve, and for the pinion (the driven) the hypocycloidal curve, putting nearly the whole of the curve on the wheel-teeth. He also applied this theory to the lifting of the hammers, both for the striking apparatus and the chimes, by using projections of an epicycloidal shape instead of the ordinary round pins in the pin-wheel. Clock-wheel cutters had heretofore paid very little attention to the geometry of the wheel-teeth. Among the other important features of the Royal Exchange clock, which are applicable to all others of similar character, whether constructed with its peculiar contrivances for insuring perfect accuracy or not, we may mention the use of hollow iron drums instead of wooden cylinders for the driving-barrels, and the use of wire instead of hempen ropes for suspending the weights. Another important arrangement is the driving of the hands of the clock, and the raising of the hammers of the striking apparatus, directly from the axis of the driving-barrel, without the intervention of any wheels and pinions. In their determination to secure a public clock of unexampled accuracy, the Gresham Committee required that the Exchange clock should have a compensation-pendulum, and that it should be so constructed as not only to show perfectly correct time upon the dials, but also to tell it with accuracy by making the first stroke of the hour upon the bell true *to a second.* This difficult work is provided for by an arrangement for moving the lever and hammer to nearly the utmost degree required before the time of striking; and causing the end of the lever, which is formed in a peculiar manner for the purpose, to remain poised delicately upon the rounded point of the projecting tooth of the pin-wheel until the moment of striking, when it is instantaneously released. The pendulum is of a comparatively simple construction, which appears well adapted for large clocks. The centre rod is of steel, and is sufficiently long to pass completely through the bob or weight, which, however, is not immediately attached to it. Upon the bottom of this rod is fixed a nut, by turning which the length of the pendulum may be nicely adjusted, and upon this stands a hollow or tubular column of zinc, through which the steel rod passes freely. On the top of the zinc column is a metal cap, from projecting portions of which descend two slender steel rods; to the lower ends of these rods the weight, which is a hollow cylinder of iron, capable of sliding freely upon the zinc column, is suspended. Thus, while both the central steel rod and the two smaller steel rods by which the weight is suspended, expand *downwards* upon any increase of heat, the position of the weight in reference to the point of suspension of the pendulum remains nearly the same; because the zinc column, though shorter than the central steel rod, expands, owing to the different nature of the metal, to an equal extent *upwards*, and consequently raises the weight just as much as it is depressed by the lengthening of the steel rod. The delicate setting or adjustment of the pendulum was effected by a contrivance suggested by Mr. Airy. The escapement is of the *remontoire* kind. The impulses imparted to the pendulum are not given immediately from the large going-train of the clock; seeing that this impulse is exposed to variations of force and resistance. They are given by a small secondary train, set in motion by the descent of a ball or weight, which is itself raised at intervals of twenty seconds by the mechanism of the going-train. The action is therefore very similar to that of a *remontoire-spring;* which, as used in some horological machines, is a small spring employed only to set the escapement in motion, it being itself wound up at very short intervals by the going-train, which receives its impulse from the prime mover. The escapement is Graham's dead-beat escapement, and has the pallet jewelled with large sapphires. In this clock has been introduced a beautiful *maintaining-power,* or contrivance for maintaining the motion of the wheels during the time of winding up; it was invented a few years earlier by Mr. Airy for the clock-work of the great Northumberland telescope at the university of Cambridge. In *fig.* 23, *a* represents the first wheel of the clock, which is mounted, as usual, upon the axis of the rope-barrel *b;* with a ratchet and click so arranged that the two must turn together whenever the rope-barrel is turned, by the action of the weight W, through the line *l,* in the direction indicated by the arrow. When the rope-barrel is turned in the opposite direction, to wind up the weight, by the action of a windlass on the axis of the wheel *d,* which engages the toothed wheel *e* on the axis of the barrel, the wheel *a* will not turn back with the barrel: *f* is the pinion which is turned immediately by connection with the first wheel *a;* and both this and the winding-wheel, or pinion, *d,* have their axes mounted in the plates of the clock-frame. The axis of the barrel and first wheel *a,* instead of being thus mounted, is attached to what may be termed a lever-frame, one side of which is seen in the cut at *g*, *h*, *i*; the lever frame itself is pivoted to the clock-

Fig. 23.



Airy's maintaining-power Fusee.

plates at *h*. To the end *i* the end of the line *k*, *l*, is attached, after passing under a running pulley attached to the weight W. *c* is an internal ratchet on the first wheel *a*, acted upon by the long click *m*, which has its opposite end attached to the lever-frame near its extremity *i*. While the clock is going in the ordinary way, the descent of W causes that part of the line marked *l* to turn the barrel in the direction of the arrow, carrying with it the first wheel *a*, the internal ratchet of which slips under, without being affected by, the click *m*. Under these circumstances the action of the weight W (through the line *l*), and the resistance of the pinion *f*, produce a certain pressure on the lever-frame at *g*; this causes the end *i* to assume a determinate position, in which it remains without motion so long as the weight continues to descend, and consequently to draw down the line *l*. But so soon as, by the operation of winding up the clock, the pressure upon *l* ceases to operate, the stress of the weight upon the portion of the line marked *k* causes the end *i* of the lever-frame to be depressed, and the click *m*, which is connected with it, to be thrust against the internal ratchet *c* with sufficient force to maintain the action of the first-wheel *a*, which turns as it were in one piece with the lever-frame round the axis *h*; thereby producing a pressure upon the pinion *f* exactly corresponding, if the axis *h* corresponds with the point at which the strain of the line *l* is applied to the rope-barrel, to the pressure which is exerted during the ordinary action of the machine.

There is one turret clock which has acquired much notoriety, on account of its size and cost, and of the extraordinary amount of controversy to which it has given rise during the long period of sixteen years; namely, the clock for the new Houses of Parliament at Westminster. In 1844 Sir Charles Barry applied to Mr. Vulliamy for plans and estimates for a clock that would strike the hours on a bell of eight to ten tons, chime the quarters upon eight smaller bells, and show the time on four dials of 30 feet diameter each. How it arose that the clock was made by Mr. Dent instead of Mr. Vulliamy: that a non professional man, Mr. E. B. Denison, became intimately mixed up with the subject: that the plans underwent numerous modifications: and that it was not till 1859 that the clock was actually fixed in its place—it would be wearisome to tell. It cannot be said that even now (March, 1860) the clock is really finished, owing to the unfortunate failure of the great bell (for which see BELL). The chief features of the mechanism are as follow. The going part is arranged for winding-up once a week; but the striking apparatus goes for seven and a half days, to allow for slight delays; and even a delay of one whole day, though it would stop the striking, would not stop the going, the latter being arranged for eight and a half days. The ponderous weights hang down a shaft 160 feet deep. Schemes have been proposed for employing both steam power and water power to wind up the clock; but at present manual power only is employed, and a most laborious duty it is. The pendulum is 15 feet long, and weighs 680 pounds; it is formed of an exterior iron tube 4 inches in diameter, with a compensating inner tube of zinc. It is a two-seconds' pendulum, with a swing or vibrating arc of 14 inches; a small weight of only one ounce, placed on a particular part of the apparatus, will alter the rate of the clock one second per day. The hammers of all the bells [BELL] are (or rather, are intended to be) worked by their levers or handles catching against cams on the edges of wheels; the great or hour-bell being worked by eighteen cams on a wheel 37 inches in diameter. On the four sides of the clock-tower are dial rooms, each an apartment of large size, traversed by mechanism which communicates motion from the clock to the hands. There is at Mechlin a larger clock dial than those at Westminster; but there is no second example of a clock with four dials 22½ feet in diameter, and provided with minute hands as well as hour hands. The frame-work of each dial, weighing no less than 4 tons, and including the quarter-hour and minute subdivisions, is of cast iron. The hour figures are 2 feet high and 6 feet apart; and the minute marks are 14 inches apart. There is a *remontoire* apparatus, to give a *visible* motion of the long hand every half minute, when the point of the hand makes a sudden leap of 7 inches. The hands weigh more than 2 hundredweight the pair; the minute hand being 16 feet long and the hour hand 9 feet. In order that (when all is completed) the indications of the clock may be visible at night, the framework of each dial is fitted in with opal or enamelled glass; provision is made for sixty gas jets behind the dial; and the clock itself will turn on and off the gas, according to the length of night at different seasons of the year.

Electrical and Illuminated Clocks. So numerous have been the novelties in the clock and watch manufacture within the last few years, that the bare enumeration of the names of inventors would occupy a considerable space. We need only, however, notice electrical and illuminated clocks.

The hopes once entertained concerning *electrical* clocks have scarcely been realised. These ingenious machines are not yet largely employed in our great centres of business. There are two kinds, which may be distinguished as electrical *dials* and electrical *clocks* proper. An electrical dial is a clock-dial, without any body belonging to it. There is a standard clock at some other place, such as the Observatory at Greenwich; there is an electric wire connecting the standard clock with the index hands of the dial; and there is apparatus for sending a galvanic current through the wire at certain equidistant intervals of time. The result of this arrangement is, that the dial-hands make a leap over a small portion of their circular course, whenever a current passes through the wire; and the figures marked on the dial give a time-value to this movement. The interval of the shocks may be a minute, half-minute, or any other amount chosen. It is quite possible to make the hands mark seconds' movements, to correspond with the pendulum-beats of a standard-clock; but in practice it is found better that the long hand should only make half-minute jumps. An electric *clock*, in the proper sense of the term, is one that carries its source of power with it, independent of any conducting wire from another building. Various modes of effecting this have been devised by Shepherd, Dent, Airy, and others. In the first attempts, electricity was employed to impel the pendulum itself; but it was afterwards found better to apply the power in raising a small weight, which may then work the pendulum after the manner of a gravity escapement. In Shepherd's Magnetic Striking Clock, the vibrations of the pendulum are caused by the repeated impulses of a fine spring: the attraction of an electro-magnet being employed solely to relieve the pendulum from the action of the spring during the return or reflex vibration. The hands are moved by separate electro-magnets, the circuit of the wires being completed and broken by the pendulum as it swings. The number to be struck is regulated by a locking-plate divided in the usual way, the hammer being moved by the direct action of an electro-magnet. Electrical clocks or electrical dials are used in astronomical observatories, and by telegraph companies, but very little in other quarters.

Intimately allied with this subject is the action of *Electric Time-balls*. These are contrivances for showing exact time *once a day only*, and in a manner to be visible throughout a whole district. The interval may be more or less than one whole day; but this is selected as being most convenient. A large ball is seen to fall at one o'clock in the day; and this fall may safely be taken, by mariners and others, as a guide for correcting chronometers, watches, and clocks. The time-ball at Greenwich Observatory, and that of the Electric Telegraph station in the Strand, may be taken as familiar examples. The Greenwich ball is a basket of wicker-work, covered on the exterior; when it descends, a piston plunges into a tube, compresses the air, and thus, makes a kind of soft cushion which enables the ball to drop without concussion—a small hole in the bottom being left for the air to escape gradually. At a few minutes before one o'clock, the ball is wound up by hand to the top of the staff. At one o'clock, to a single second, the standard clock in the observatory, by means of delicate mechanism, sends a current of electricity which loosens a trigger and lets the ball sink. The time-ball in the Strand, of later construction than that at Greenwich, exhibits many improvements in detail. Several others have since been established at the outports.

The rendering of clocks visible at night is one of the many improvements introduced in recent years. The illumination is effected in many ways. At the Horse Guards in Whitehall, light is thrown on the face of a dial from a gas-flame hidden behind a parapet. The more usual method is to make the dial either wholly or chiefly of semi-opaque glass, and to manage the lighting in the way just noticed concerning the (prospective) arrangements for the Westminster clock. Such dials, however, are not so conspicuous and convenient during the day as those of ordinary construction; and it is difficult to maintain the hands in a well-adjusted condition. A suggestion w made a few years ago for the use of semi-opaque hands and figures on a transparent dial; with gas-lights in a black-cloth lined chamber behind the dial, and reflectors to throw the light on all the surrounding objects except the black cloth. General Perronet Thompson has suggested a night clock, with twelve holes cut in a disc for the twelve hours, and a radial slit near the centre to represent a hand; the disc is to revolve, and gas-lights to be placed behind it. In a fine new turret-clock set up in the Exchange at Leicester, in 1859, the lighting at night is effected by placing two large lenses before the gas-burners, connected by a pierced tube of jets; so as to light one burner from the other, if either should go out during the day-time, when the gas is turned very low. The illumination is evenly diffused over the dial without glare, and without the position of the burners being distinguishable.

Clock and Watch Trade.—We will conclude with a few observations on the manufacture of clocks and watches, regarded in its commercial and industrial features.

So far as concerns our own country, the manufacture is chiefly conducted in and near London, Coventry, and Prescot. In London, the district of Clerkenwell is the head-quarters of the trade. The *movements* of watches are made almost wholly at Prescot and other places in Lancashire; the London workmen only make the other parts, and put the whole together. A Clerkenwell watch-manufacturer is one who buys movements from Lancashire, employs smaller tradesmen to fabricate the other parts, and brings the watches into a finished state. These tradesmen are not mere workmen; they are small master tradesmen. One supplies the motion-work, another the spring, another the escapement, and others the case, dial, glass, &c. These secondary masters subdivide the work to a degree almost incredible. Every kind of escapement has many different workmen specially employed upon it; and so has every kind of motion work, hands, dials, &c.; insomuch that an ordinary London watch passes through considerably more than a hundred hands, even after the movement has been brought from Lancashire. Nearly all the workmen thus employed labour at their own houses: the work being quite of a handicraft character, in which very little machinery is employed. The men acquire considerable skill, each in his particular craft; but it is a system unfavourable for enterprising inventions and cheapening processes, seeing that each man's tact and experience are confined to one very limited range of work. As a movement in the right direction, a Horological Institute was founded in Clerkenwell in 1858—"to develope and improve everything relating to the art, by means of a library of books, a reading-room, a museum of tools and machines or models, the reading of lectures and essays, and the publication of a Journal." The principal makers of church and turret clocks live in London, and manufacture nearly the whole of the machinery on their premises. Prescot exports watch movements to America, as well as supplying the home trade; more machinery is employed in this trade, and to this fact perhaps may in part be attributed the settlement of it in a county celebrated for its delicate machinery.

Switzerland is celebrated for its watch-making. The women and children in Neufchâtel, and some other cantons, learn certain parts of the trade, and find employment in this way, either all through the year, or in the winter, when little out-door work can be done. There is a minute delicacy in Swiss watches which those of England seldom exhibit; and the selling price is such as no English maker can compete with. On the other hand, the *best* English watches are not equalled for strength and accuracy by any others in the world. A London manufacturer, Mr. Bennett, has within the last few years endeavoured, by means of letters, pamphlets, and lectures, to foster the introduction of the Swiss system into England, as a means of increasing the range of employment for women, lowering the prices of watches, and increasing the sale. In the meanwhile, machinery is gradually being brought into the trade in Switzerland and the adjacent part of France. Brukker's small brass clocks, saleable in London retail at only five shillings each, would be a commercial impossibility without the aid of machinery. At Besançon, machine-made watches are now produced in large numbers; the product in 1848 was about 28,000; and in 1856 it reached 160,000, worth about 320,000*l*.

America has organised a very large system of clock manufacture—quite on the factory system—chiefly in Connecticut. There is one company which employs 250 hands in a compact factory; many of the operatives are boys and girls; and the product is 600 clocks per day. Much wood-work is employed in the cheaper American clocks; but machine-stamped brass clocks are also manufactured very largely. Dr. McGowan, United States consul at Ningpo, wrote home to his countrymen in 1853, giving some curious details concerning the clock-trade in China: and offering hints whereby America might successfully open a market in that quarter.

HORSE POWER. A term used in mechanical engineering to express the unity of comparison of the power of steam, or water power, machines, which is based upon the assumption that a horse is able on the average to perform a certain definite quantity of work within a given time. Constructors of engines differ in their estimates of the value of an average horse power, some reckoning it to be equal to 27,500; some to 29,000; and others to 33,000 lbs. raised one foot high per minute. The latter estimate was the one adopted by Watt; and it is also the one most generally followed both by English and foreign constructors. On this basis a horse power is said to represent a load, in pounds, raised one foot in vertical height, of 550 lbs. per second; 33,000 lbs. per minute; or 1,980,000 lbs. per hour; or the effort which 7 men working for a short time could exert.

The formula usually adopted in calculating the horse power of low pressure steam engines is as follows:—Calling the effective pressure of the steam upon the piston (beyond the power required to overcome the friction, and the incidental services the engine is called upon to perform, such as the movement of the feed-pumps, the air-pumps, &c.)—calling this effective pressure, supposed for instance to be 7 lbs. per square inch, A; the diameter of the piston in inches, D; and the velocity of the piston in feet, per minute, V; we have the formula $x = A\frac{\frac{1}{4}\pi D^2 V}{33{,}000}$, or, in round numbers $= \frac{D^2 V}{6000}$. In condensing and expansion engines this formula ceases to apply; for the point in the stroke at which the steam is cut off materially affects the effective pressure; and it is by no means rare to find at the present day that steam-engines will exert a force actually three times as great as the theoretical force indicated by calculation. As the proportions of the various parts of engines and boilers are calculated with reference to the horse power of the engines, this uncertainty in the mode of ascertaining the unity of work is unfortunate, and numerous remedies have been suggested; such, for instance, as the calculation of the force by means of the weight of steam produced. No confidence can, however, be placed in them, and the old formula is still generally followed.

Two very rude empirical formulæ are adopted by some practical engineers for calculating the horse power of an engine, which may sometimes be of convenient application, as furnishing an approximate means of estimating the value, without, however, attaching any precise importance to the indications so given. They are, calling the diameter in inches, a; the number of strokes, b; the length of the stroke in English feet, s; then $\text{HP} = \frac{a^2 \times \sqrt[3]{s}}{47}$; or, $\text{HP} = \frac{a^2 \times bs}{6000}$.

The horse power of a water-fall is really indicated by multiplying the cubic quantity of water falling over the shuttle by the height of the fall and by 62·5—the weight of a foot cube of water being 62·5 lbs. In the best descriptions of water-wheels, however, a very large portion of the real power is lost by the friction of the machinery, and by the passage of a certain portion of the water without its striking the wheel; and in the more unfavourable varieties the loss is so great as to materially modify the calculated results. Thus Mr. G. Rennie calculates that the effective results as compared to the theoretical ones are, for overshot wheels as 27 or 30 to 100; for breast wheels as 45 or 50 to 100; and for undershot wheels as 60 or 80 to 100. Calling then the quantity of water falling, Q; the height of fall, H; and the co-efficient of the real effective power, expressed decimally, C; we have the formula for a water-wheel $\text{HP} = \frac{QH \times 62{\cdot}5}{33{,}000} C$.

As the usual application of the power of a horse is for the purpose of drawing a load on roads, it may be as well to state, that the useful result of such application must evidently depend on the state of the surface of the roads themselves. This branch of applied science has been studied by Gerstner, Parnell, Gordon, &c.; and the results of their investigations are expressed in the following empirical formulæ. Calling the power exerted, estimated in pounds, P; the weight of the waggon, W; the load, w; the co-efficient for the surface under consideration, c; and the velocity in feet per second, v; we have $P = c\left(\frac{W+w}{98} + \frac{w}{40} + v\right)$. On an inclined road, this formula becomes $P = c\left(\frac{W+w}{93} + \frac{w}{40} + v + \frac{h}{l} \times \frac{W+w}{1}\right)$; in which h is the vertical rise, and l the horizontal length of the incline. The value of c is usually given as $= 2$ on a paved road; $= 5$ on a well made broken stone road in a good state; $= 10$ on a similar road when wet and muddy; $= 13$ on a dry gravel or broken flint road; and as $= 32$ on a wet and muddy gravel or broken flint road. Coulomb, and the earlier writers on dynamics, considered that the ordinary power of a horse, at a dead pull, was equivalent to 420 lbs.; and that he was able to exercise the above force most advantageously, when walking at the rate of 3 feet per second. Smeaton gives the useful effect of a horse walking at that velocity as being equivalent to 189 lbs.; this velocity is nearly at the rate of 2 miles per hour; but when the velocity becomes 3 miles per hour, the useful effect falls to 80 lbs. Telford gives 200 lbs. as the actual work of a horse raising a weight over a pulley out of a well, for eight hours in a day, at the rate of 2½ miles per hour; he also says that in a cart, a horse will draw more than 2000 lbs. For more extended statements on this subject, see the article ANIMAL STRENGTH. A great deal of curious information may be likewise obtained upon the subject of horse power as usually exerted, in Gordon's 'Treatise on Locomotion,' 1834. Borgni's 'Traité complet de Mécanique,' 1818, contains, however, the most complete digest of the experiments on the power of men and of animals.

HORSE-RADISH.—*Medical Properties of.*—Horse-radish is a cruciferous perennial herbaceous plant, growing in Alpine meadows, and along the banks of rivers, as well as on the sea-coast in the south and south-eastern parts of Europe, called Cochlearia Armoracia (Linn.) or Armoracia rusticana (Wettereau). The root is the officinal part, and is always obtained from cultivated plants, as it is enjoined to be used in a fresh state. The root is solid, fleshy, tapering, from one to two feet long, and when bruised or scraped into shreds, emits a highly acrid penetrating odour, which causes a secretion of tears when received by the eyes: put in contact with the skin, it speedily causes rubefaction. The taste is more or less acrid, according to the season of the year or the age of the plant; young plants possess much mucilaginous starchy and saccharine matter, by which the pungency is lessened.

The analysis by Gutzet shows its composition to be acrid and very volatile oil, bitter resin, extractive, sugar, gum, starch, woody fibre, vegetable albumen, acetic acid, with acetate and sulphate of lime. A little sulphur also exists in it. The volatile oil is the active principle. This is of a pale yellow colour, heavier than water, and so volatile that a single drop of it can fill a large room with a penetrating odour of horse-radish. In this respect it resembles the volatile oil of mustard. The taste is at first sweetish, afterwards burning and acrid. It has a sensible effect on the brain. When applied to the skin, it causes violent inflammation and rubefaction. It is identical with oil of mustard. [SINAPIS, in NAT. HIST. DIV.] It is sparingly soluble in water; freely in alcohol. The outward application of horse-radish causes vesication; the internal application causes sensible warmth of the stomach, with augmented power of digestion. A warm infusion excites vomiting, in the same way as mustard does. This kind of emetic is useful to rouse the stomach from the insensibility consequent on narcotic poisons being taken, but it must not be forgotten that violent or even fatal inflammation of the stomach may ensue if vomiting do not occur, and the stomach-pump is a more certain means of emptying that viscus.

Horse-radish is well known as a condiment taken with beef, fish, and other kinds of food difficult of digestion. Its powers are heightened by associating it with vinegar, as in the horse-radish sauce.

The officinal preparations are the Infusum Armoraciæ Comp. This, when made with warm water as ordered in the Pharmacopœia, soon spoils, notwithstanding that some compound spirit of horse-radish is added to it. It would be much more advantageous to make it with cold water, especially as its power depends upon a principle of such remarkable volatility. The compound spirit is employed as an adjunct to diuretic and other medicines. Horse-radish scraped down into shreds and digested in red wine forms a Vinum armoraciæ, which is eminently useful in warding off a relapse of intermittent fever, when the employment of it is persevered in for some time. Digested for an hour in vinegar, it is an excellent gargle against hoarseness.

(Dierbach, *Die Neusten Entdeckungen in der Materia Medica*, i. p. 81.)

HOSIERY MANUFACTURE. The principal seat of the hosiery manufacture in England is in the three midland counties of Leicester, Nottingham, and Derby. In the first of these woollen hosiery forms the principal branch of the manufacture, while in Nottinghamshire the material chiefly used is cotton, and in Derbyshire silk goods are mostly made.

The stocking-frame, by means of which this manufacture is carried on, is, next to the common warp and weft loom, the oldest machine in existence applicable to textile fabrics. It was invented about the close of the sixteenth century by the Rev. William Lea, of St. John's College, Cambridge; but a considerable time elapsed before the produce of this frame took the place of the trunk-hose then worn by all who could afford such an article of dress. For this reason Mr. Lea settled at Rouen in Normandy, where his manufacture was carried on under the patronage of Henri IV.; but the assassination of the king and the political troubles brought on by that event caused the abandonment of Mr. Lea's establishment, and that gentleman shortly after died in a state of poverty at Paris.

From the period of its first invention the stocking-frame received no considerable improvement until quite recent times. Frames, however, with a rotatory action, and worked by steam-power, have been successfully brought into use at Nottingham, and bid fair to supersede altogether the use of the old reciprocating engine. The economy in the process of manufacture thus effected is very great. The working of a rotatory machine impelled by steam-power, in which twelve fashioned stockings are made at the same time, requires the superintendence of only one man and a boy; whereas in the old frame but one stocking can be made at once by a single workman. The substitution of steam-power frames for the old hand frames produced at first some distress among the framework knitters; but the great extension of demand which is always found to accompany a considerable cheapening of any manufacture, lessened this evil by causing employment for an increased number of hands. The cotton branch of the hosiery manufacture differs from the woollen and silk branches in the relative proportions of the cost of labour as compared with the cost of the material. In cotton hosiery the cost of labour constitutes from two-thirds to five-sixths of the value of the goods; while in woollen hosiery the labour does not exceed two-fifths of the value; and in silk goods the proportionate cost of labour is still smaller.

It is difficult to describe the processes of this manufacture without the use of many wood-cuts; and even then the routine is not well understood without seeing the machines actually at work. The hosiery or frame-work manufacture is a peculiar kind of interlacing. Instead of being a series of cross threads woven in a loom, it is a series of loops or links, so connected as to possess both strength and elasticity in a remarkable degree. It is a continuous thread which is thus linked around itself; in a way which bears a good deal of resemblance to many kinds of ladies' netting and crochet work. The article made in the stocking frame is not a stocking, but a piece of knitwork cloth, which is afterwards sewn up into the form of a stocking by needle and thread. Hence, there are three kinds of operatives engaged; the *winders*, who put the thread into or on the machine; the *frame-work knitters*, who work the thread up into a knitted fabric; and the *seamers*, who make the stockings out of the pieces thus produced. The winders are generally children, who can each wind thread enough for half a dozen machines; the knitters are men, women, and youths, who hire both the winders and the seamers; and the seamers are women. Some of the stocking-frames are owned by the frame-work knitters; some are let out to the men by the owners, at so much per week for each frame; while other persons are the renters of what is termed a 'shop of frames,' containing eight or ten frames; these, with standing-room to work in, they let to the workmen, at so much per frame per week. The master manufacturer gives out his thread, and the workman returns this thread in the form of stockings, the work being paid for at so much per dozen pair.

We have spoken only of hosiery, but many other articles besides stockings are made of this linked fabric. Gloves, waistcoat-pieces, mitts, pantaloons, drawers, braces, webs, comforters, caps, jackets, leggings, and various other articles—are made nearly in the same way, and of the same material. The processes for worsted, cotton, and silk are nearly analogous; those for silk requiring, however, the greatest care. Some progress, as has been remarked above, has been made towards the manufacture of hosiery by means of steam power.

Ireland is gradually advancing in this as in many other branches of industry. At Balbriggan there is a hosiery manufacture, from which specimens of cotton hosiery are issued, of a degree of fineness such as has never perhaps been equalled; one dozen pairs of ladies' full size stockings weigh only nine ounces. Cotton stockings of a peculiar kind of open work are also manufactured in the same town.

Among various inventions relating to the manufacture of looped and other hosiery fabrics, is one by Messrs. Keeley and Wilkinson. Several threads are here used instead of one, differing in materials and possibly in colour; these are so looped that any one or more threads may be completely enveloped by the other; and the mode of interlacing is such that, in the event of failure of a loop, it does not necessarily cause the general running or failure observed in most hosiery goods under similar circumstances. By this system, gloves or stockings may be composed of three threads, one of cotton and two of silk; the silk being shown both on the outside and the inside, and the cotton hidden between them. The cotton stratum may consist of two threads instead of one. A substitute for expensive silk stockings or gloves is thus produced. Many improvements have also been made in the manufacture of looped fabrics required to be narrow at one end, like braces; the usual way is to sew the material transversely, and then draw the thread so as to give a closer texture to the narrower part; but the frames are sometimes so adjusted as to weave the wide part, and then produce the narrow part with the same number of threads by a change in the action of the mechanism. Another novelty consists in the making of gloves or mitts, in such a way that the inner surface of the knitted fabric shall exhibit a pile or velvet texture. India-rubber is now very ingeniously employed in gloves and other knitted fabrics, to give elasticity and closeness of fit to particular parts. The circular knitting, or hosiery machines, are efficient contrivances for producing garments without a seam; the construction is very intricate; and some are so contrived as to produce a pattern or device as well as to produce the fabric itself.

The hosiery manufacturers of this country, at least those engaged in making cotton stockings, are much interfered with in the foreign trade by the competition of Saxony. At Chemnitz the manufacture of cotton stockings is carried on very extensively. There are large establishments in which circular frames are worked by steam power, with steam presses and steam irons to finish the goods. The women who tend these machines receive little more than 2*s.* per week on an average; but this sum will go as far as 5*s.* in England, as a means of support. The Chemnitz hosiery is exported largely to the United States, where it proves a formidable competitor to English produce.

It has been stated in a former paragraph that the stockingers of the midland counties follow a peculiar system in hiring the frames with which they work. Hence arises a condition of things against which they are always complaining. With the exception of the Spitalfields silk weavers, few artisans in England have more frequently solicited the protection of the legislature than the stockingers or frame-work knitters, especially those engaged in the worsted trade of Leicestershire. The men and their families are always poor, let the state of trade be brisk or slack; they seem bound to their employers by shackles which they cannot throw off; and there is a general tone of despondency in all their communications on the subject. They state that, whatever be the nominal wage for making a dozen pairs of stockings, the stoppages are so great, for frame-rent and other items, that their net earnings, even for adult men, do not exceed 8*s.* or 10*s.*

per week. Among numerous appeals to the legislature, one in 1844 made a considerable impression; it was a petition signed by 25,000 frame-work knitters. The government employed Mr. Muggeridge as a commissioner, to make minute inquiries in the three midland counties. He examined no less than 600 witnesses, and came to a conclusion that the legislature should step in to protect the artisans. All the leading statesmen, however, felt that any interference between employers and employed on a matter of wages lies beyond the functions of the British legislature; and nothing particular was effected. After many years' more complaining, a Committee of the House of Commons investigated the subject in 1857. A volume of 700 folio pages, containing an immense mass of information, was the result of this inquiry; and a few words from the Report of the Committee will suffice to show the singular commercial economy of the trade. Foreign competition, improvements in machinery, and changes of fashion, have tended to lower the wages of those who work on the old hosiery-frames; and this lowering, it is contended, is aggravated by the mode of paying wages. "The middle-man supplies the workman with frames and other machinery, sometimes belonging to himself, and sometimes hired of the manufacturers and other owners. When he settles with the workman, he deducts out of the gross price per dozen of the work performed—first, a sum as rent for the use of the frame; secondly, a sum for winding the yarn, which is a necessary operation; thirdly, a sum to remunerate himself for the use of the premises where the work is performed, and for the standing-room of the frame; and fourthly, a sum for his trouble and loss of time in procuring and carrying to the workman the materials to be manufactured, for the responsibility to the manufacturer for the due return of the materials when manufactured, for superintending the work itself, for his pains in sorting the goods when made, and for re-delivering them at the warehouse of the manufacturer. The manufacture is carried on, in many instances, at the houses of the workmen, and in places distant from the residence of the manufacturer; with no communication between him and the workmen except by the intervention of the middleman." It has become a custom almost universal in Leicestershire, to charge 1*s.* per week rent for a frame, whether it be old or new, and whether it be worked by man, woman, or child; this, it is quite certain, yields a very handsome profit on the capital expended in purchasing the frame. One manufacturer, in 1857, employed 2000 frames, one half owned by himself and the other half by middlemen; but all these frames alike were charged 1*s.* per week to the knitters who used them. It is nevertheless evident that this is a matter with which the legislature can hardly deal; the net actual earnings will, in spite of legislation, depend on the ratio between supply and demand among manufacturers, middlemen, and workmen; it might be altered in name, but not in substance. The Committee of 1857, like the Commission of 1844, failed to produce any legislation on the subject.

A few figures relating to the export and import of hosiery, in 1857, will suffice as an illustration applicable to recent years:—

EXPORTS.

	Dozen Pairs.	Declared Value.
Cotton stockings	1,020,000	£312,000
Cotton hosiery and small wares	..	325,000
Silk stockings	9,300	13,000
Silk hosiery and small wares	..	36,000
Silk and cotton stockings	8,700	6,000
Silk and cotton hosiery and small wares	..	7,000
Worsted stockings	190,000	133,000
Worsted hosiery and small wares	..	215,000

IMPORTS.

	Dozen Pairs.	Average Value.
Cotton gloves	170,000	3½*d.* per pair.
Cotton stockings	450,000	7*d.*, stockings. 4*d.*, socks.
Worsted gloves	6,400	5*d.*

Our exports were chiefly to Australia and the United States; the imports chiefly from the Hanse Towns.

HOSPITAL (sometimes called simply *spital*, from the French *hôpital*), a place endowed for the reception of the sick or support of infirm persons. The first hospital for the sick is said by Monçez to have been founded in the latter part of the 4th century. Hospitals intended merely for the relief of poor and indigent persons in England are peculiarly called *Alms-houses.* At an earlier date hospital signified a place of shelter or entertainment for travellers upon the road, more especially for pilgrims. Spenser in the 'Fairy Queen,' uses the word in this sense:—

> "They spy'd a goodly castle, placed
> Foreby a river in a pleasant dale,
> Which, chusing for that evening's *hospital*,
> They thither march'd."

The Maison de Dieu at Dover, St. John's Hospital at Warwick, and some others, were expressly founded for the reception and entertainment of pilgrims and travellers.

Many of the charitable endowments in England are called hospitals, and are incorporated bodies, consisting of a master, brethren, and occasionally other members. Some of these foundations have also schools attached to them. But the name is now more generally restricted to places for the reception of sick, or wounded persons, and such hospitals are very numerous in the United Kingdom. In London, the chief exceptions are the Foundling Hospital, for the reception of illegitimate children, abandoned by their fathers; Christ's Hospital, an educational establishment for the teaching of classical learning; Chelsea and Greenwich Hospitals for the reception of aged and infirm soldiers and seamen; and Bethlehem and St. Luke's Hospitals for lunatics. Medical and surgical hospitals are established in every large town throughout the kingdom; and in London there are many. The oldest, and perhaps even yet the most important, are St. Bartholomew's, founded in 1122; St. Thomas's, changed from a religious establishment to a medical hospital in 1551; and Guy's, opened for the reception of patients in 1725. These three are supported by endowments, and are very wealthy. All the other hospitals for the sick, in the country, as well as in London, are supported mainly by voluntary contributions. As to the management of their revenues and their general superintendence, hospitals are on the same legal footing as other charities.

The construction of hospitals is a subject which has recently engaged much attention among architects, physicians, and sanitary reformers. The systems which have found the ablest advocates are those known as the *pavilion* and the *corridor;* but a discussion of their respective merits would evidently be beyond our province. It will be enough to say that hospitals for the sick require to be well situated, thoroughly drained, to have the rooms or patients' wards lofty, well lighted and ventilated, and sufficiently and equably warmed. Without these requisites the care and attention of the physician will be either in vain, or materially obstructed.

HOSPITALLERS. Hospitaller, in its literal acceptation, means one residing in an hospital, in order to receive the poor or stranger; from the Latin *hospitalarius*, a word found only in the language of the lower age. The *Knights Hospitallers* were an order of religious formerly settled in England, who took their name and origin from an hospital built at Jerusalem for the use of pilgrims going to the Holy Land, dedicated to St. John Baptist. The first business of these knights was to provide for such pilgrims at that hospital, and to protect them from injuries and insults upon the road. They were instituted about the year 1092, and were very much favoured by Godfrey of Bouillon and his successor Baldwin king of Jerusalem. They followed chiefly St. Augustine's rule, and wore a black habit with a white cross upon it. They soon came into England, and had a house built for them in Clerkenwell, London, in 1100; and from a poor and mean beginning obtained so great wealth, honours, and exemptions, that their Superior here in England was the first lay-baron, and had a seat among the lords in parliament; and some of their privileges were extended even to their tenants. The order was suppressed in England by the 32 Hen. VIII., c. 24, on the ground that the knights sent money out of the kingdom, abetted the usurpations of the pope, defamed the king and his subjects; adding that their revenues would be better spent in the defence of the kingdom.

There were also sisters of this order, of which one house only existed in England, at Bucklands in Somersetshire.

Upon many of their manors and estates in the country the Knights Hospitallers placed small societies of their brethren, under the government of a commander. These were allowed proper maintenance out of the revenues under their care, and they accounted for the remainder to the grand prior at London. Such societies were in consequence called Commanderies. What were commanderies with the Hospitallers were called Preceptories by the Templars, though the latter term was in use with both orders.

The Knights Hospitallers had several other designations. They were at first called Knights of St. John of Jerusalem; afterwards, from their fresh place of settlement, Knights of Rhodes; and after the loss of that island in 1522, Knights of Malta, from the island which had been bestowed upon them by the emperor Charles V. The order still exists under this title, and the chief, or grand commander still resides at Malta.

(Tanner, *Notit. Monast.*; Dugdale, *Monasticon Anglicanum*; Collier's *Ecclesiastical History of Great Britain.*)

HOSPODAR is the title of the persons formerly sent by the Turkish sultan to govern Moldavia and Wallachia, the two provinces north of the Danube. These governors for more than a century were taken from the principal Greek families of the Fanar, such as Maurocordato, Soutzo, Caradja, Morousi, Callimachi, Ypsilanti, &c. They assumed the title of princes, and were addressed as "Most Serene Highness." They held in their respective capitals, Bucharest and Jassy, a numerous court, consisting chiefly of Fanariote Greeks, and were in fact almost absolute sovereigns during the time of their administration. This however might be shortened at the pleasure of the Porte, which often recalled them, and put them to death. At the time of the Greek revolution in 1821 the Hospodar of Moldavia, Prince Michael Soutzo, escaped into the Russian territory, and his relative the Hospodar or Prince of Wallachia was poisoned. The present government of those two principalities is vested in one hospodar, elected separately by the two principalities; who is assisted by representative assemblies, the two principalities having acquired a sort of independence, though acknowledging the suzerainty of the Turkish sultan, whose consent is necessary to the instalment of the hospodar.

HOTBED, a name given by gardeners to a heap of fresh stable litter in a state of fermentation, upon which a glazed box is placed for the cultivation of certain plants requiring heat and moisture in greater quantity than those agents exist in the external air. Formerly hotbeds were more exclusively used for various purposes in horticulture than they now are. This is owing to the perfection to which other means of producing and applying artificial heat have now attained; but still, for the growth of cucumbers and melons, raising seeds of tender annuals, and of other plants, either culinary or ornamental, hotbeds continue to be advantageously employed, as they likewise are for the striking of cuttings.

Hotbeds may be formed of various substances, such as unrotten dung, tan, leaves, or a mixture of these with moist litter; in short, any substance capable of producing and retaining fermentation, and which will admit of being built up so as to support a frame with sashes. The substance however that is most generally used is fresh stable-dung; the preparation which it requires consists in its being thrown in a heap, and also watered, if it contain much dry litter; and as fermentation proceeds it should be turned two or three times, and mixed thoroughly in the process.

The situation in which hotbeds ought to be formed should be dry, open to the south, and well sheltered in every other direction, either by walls backed by high and close-growing trees, or by very close and lofty hedges. Such extensive shelter, though desirable, cannot always be obtained; but some mode should be employed to break the force of sweeping winds. The basis on which the bed is to be formed should be marked out from 4 to 6 inches each way beyond the dimensions of the frame intended to be placed upon it; and if faggots or a layer of brushwood be laid as a foundation, it will admit heat completely under when the bed requires the application of a *lining*, which is a quantity of fresh materials added to the outside, should a diminution of heat require a new supply. The bed is then built of successive layers of the prepared materials, each layer being beaten tolerably compact with the fork as it is laid on, to the height of 4 feet in front, and 4 feet 9 inches at the back: the sides and ends should be quite perpendicular. The top layer should be as free from litter as possible. When thus finished, the frame and lights are placed upon it, and as soon as the violence of the fermentation has diminished, mould is put in; and when the latter has acquired a proper temperature the plants are introduced. Instead of mould, rotten tan, or leaf mould, or sand, is spread over the surface of the bed, when pots containing seeds or cuttings are to be plunged.

As soon as the heat of the bed begins to decline, a *lining* of fresh materials must be applied. This however may be composed of substances that have not undergone any previous fermentation, and may consist of fresh stable-dung, merely shaken up as it is placed against the sides of the bed, or of grass mowings, or of leaves, or of a mixture of such substances.

A bed formed of well-prepared materials, and raised to the height above mentioned, will be sufficient for any purpose for which a strong bottom-heat is required; but a very mild bottom-heat is frequently all that is wanted. In this case the bed is made lower and more compactly beaten or trodden. Substances that ferment violently are likewise excluded from its composition.

It sometimes happens that, notwithstanding every precaution with regard to its formation, a hotbed will become too hot for plants or seeds that may have been placed above it. In this case the only remedy is to remove the plants until the hotbed has been remade, with the addition of some materials the fermentation of which is slower and less violent. Gardeners sometimes attempt to avoid the trouble of doing this by piercing the sides of the hotbed with holes for the egress of heat; but this is seldom an effectual remedy for the evil.

HOTCHPOT. (Law.) The word has been thus quaintly explained by Littleton:—"It seemeth that this word hotchpot is in English a pudding, for in a pudding is not commonly put one thing alone, but one thing with other things together." The common law prescribed the rule, that where a daughter to whom lands had been given in frank marriage claimed a portion of the lands descending upon her together with her sisters from the father in fee simple, she should not take any share unless she mixed and blended the lands given to her in frank marriage with the descended estate, so that they might be equally divided among all the daughters. The rule is founded upon the same grounds as the Collatio bonorum of the civil law. ('Dig.' xxxvii. 6; 'De Collationibus.') The statute 22 and 23 Chas. II., c. 10, s. 5 (the Statute of Distribution) provides, that in making distribution of the personal estate of intestates, advancements made by them in their lives to their children shall be brought into hotchpot.

HOTHOUSE, in horticulture, is a structure in which exotic plants are cultivated under circumstances approximating as closely as possible to those under which they naturally exist; or it is used for accelerating the production of flowers and fruits of either indigenous or exotic plants. Hothouses appropriated to the latter purposes are very frequently termed *forcing-houses*.

In the beginning of the 17th century that description of hothouse generally termed the *greenhouse* began to be constructed in Germany; and one in the Apothecaries' Garden at Chelsea is mentioned by Ray in 1684. These, like many others of later construction, had glass only in the front, which was perpendicular; and the mode of applying artificial heat exhibited little more knowledge of means for the end than the remains of flues found in the ruins of the dwelling-houses and baths of the Romans.

In 1724, when Switzer published his treatise entitled 'The Practical Fruit Gardener,' the principles of managing hothouses were still very imperfectly understood; for he observes, p. 305, that "Peaches, nectarines, and apricots don't love to be forc'd; at least the fruit is very seldom good: there being much occasion to keep the glasses close, the fruit is always rendered flat and insipid. This is not pure speculation, but the result of the practice that I have observed in the glass houses at Brompton Park."

Considerable alterations, particularly in houses for grapes, were made towards the end of the last century. The most material improvement was the substitution of a slanting glass roof for a perpendicular glass front; but the advantages of this were much diminished by the heaviness of the sashes, and the large quantity of opaque matter which it was thought necessary to employ in order to ensure the durability of such structures.

In the present century great advances have been made in hothouse building, and more particularly since 1815. The application of heat by steam or hot water, and the admission of a greater quantity of light by glazing on metallic bars instead of wooden sashes, are the principal features of these improvements.

The principles by which the construction of hothouses must be governed have reference to the three great agents in vegetation—*heat*, *moisture*, and *light*.

With regard to *heat*, the building must provide for a sufficient amount to raise the internal temperature of the house, from that of the lowest degree of external air that occurs in this climate, to that of the highest which prevails for any length of time in the countries of which the plants intended to be introduced are natives. This rule is without exception as far as plants strictly tropical are concerned; a slight relaxation may be allowed in some cases with regard to plants of temperate climates, such as, for instance, the vine when it is only intended to be forced late in the season, after the severity of the winter is over. With regard, however, to vineries intended for early forcing, the extremes of temperature should always be made the data for calculating the extent of the requisite heating power. The consequences of too limited a heating power will, in many instances, be exhibited for several years. Vines in a forcing state have been so affected by the extreme cold of a single night, that the crop has been not only lost, but the vines themselves so much injured as not to be worth preservation. This shows the necessity of always providing for extreme cases, since a deficiency of heat for only a few hours may occasion an injury that cannot be remedied in as many years.

Moisture is of very great importance, and a due proportion of it is frequently more difficult to maintain in the atmosphere of the house than heat, and more so by some modes of heating than by others. It therefore follows, that as all applications of fire-heat have a tendency to produce too great a degree of dryness, that mode is the best for the growth of plants which allows of the greatest quantity of vapour to remain uncondensed in the atmosphere of the house.

Some tribes of exotic plants, natives of the torrid zone, are adapted for existing under a very dry atmosphere. Instead of developing a thin expanded foliage, they form thick succulent masses, which no degree of atmospheric dryness seems to injure. Plants of such a nature of course require a *dry stove*; and a period of extreme dryness is perhaps as necessary for their future vigorous development as the cold of winter is to the deciduous trees of the north. But with regard to the generality of plants from tropical regions, a very different atmosphere is necessary. Within the tropics, the dryness of the air seldom exceeds 10° of Daniell's hygrometer; whereas, in the neighbourhood of London, between 20° and 30° are frequently indicated during the day. In tropical countries the air is saturated with moisture during the night, or at least it is but very rarely otherwise in the open air. But if due precautions be not taken and temperature only be attended to without regard to moisture, a degree of dryness will prevail at *night* in hothouses, which is double that of the tropic during the *day*. Artificial heat having therefore this excessive desiccating tendency, the necessity becomes obvious of adopting such modes of construction and heating as will afford the best means not only of supplying but of maintaining moisture; for vapour may be raised till the air of the house is at the point of saturation, and yet causes may operate so as to occasion a speedy condensation and a consequent dryness.

Light cannot be admitted too freely into hothouses. This will appear evident from the circumstance of the most transparent medium that can be used reflecting a great proportion of the sun's rays when they impinge obliquely on its surface. According to Bouguer's 'Table of Rays reflected from Glass,' when the angle of incidence is 85°, as much as 54 per cent. of the sun's rays are reflected; and at angles of incidence of

80°,	70°,	60°,	50°,	40°,	30°,	20°,	10°,	1°
41,	22,	11,	6,	3,	2,	2,	2,	2

per cent. are reflected, omitting fractions.

Besides this, in wooden roofs, even although of good construction, 22 per cent. of the rays of light are obstructed by the rafters, &c. In iron roofs the obstruction is reduced to 7 or 8 per cent. In the case of a house fronting due south, the rays of the sun at 6 A.M. will run parallel with the roof; at 7 A.M. 30 per cent. of the rays will be reflected from the glass alone, independent of the quantity from other causes. At 8 A.M. 10, and at 9 A.M. about 4 per cent. will be reflected. From this time till 3 P.M. the proportion reflected will be only from 2 to 4 per cent. If we therefore take from 6 A.M. to 6 P.M., a length of time from which the tropical days never differ much, we may calculate the loss of rays to be from

Reflection of glass, say on an average . .	10 per cent.
Obstruction from rafters (iron) . .	8 „
Ditto from glazing laps	5 „
	23 per cent.

But if wooden rafters are employed, 15 per cent. additional must be added, making in this case a loss of 38 per cent. In old and heavily constructed houses, it certainly would not be too much to state the loss of rays at 50 per cent.; and under this privation of light it is not surprising if the plants are found to exhibit a yellow sickly foliage.

The above calculation of the reflection of rays is made on the supposition that the *pitch* or elevation of the roof forms an angle with the horizon corresponding with the latitude of the place, say for London 51½°, or forming an angle with the back wall equal to the complement of the latitude, or 38½°. The period of the season is that of the spring or autumn equinox. A plane elevated to the above angle would have the sun's meridian rays more nearly perpendicular throughout the year than could be the case with any other elevation. This however is not the most eligible angle of elevation, except perhaps in the case of a very early forcing vinery or peach-house, where the direct rays of the sun are more especially required at an early period of the season. The principal objection to this elevation is, that it occasions the house to be built too high in proportion to its width, and the heat accumulates in the upper angle where it is least wanted; in short, the higher the back wall, the colder is the air of the house at its base, and the warmer at the top, compared with the mean temperature throughout the house. It will therefore be proper to inquire how far the above elevation may be deviated from without greatly affecting the transmission of light. If the slope of the roof were lowered so as to form an angle of 20° with the horizon, the loss from reflected rays at noon would average about 3 per cent.; but in the morning and afternoon the loss would be considerably greater, more especially in the winter season; and it is of course proportionally less in summer. So far therefore as light is concerned, any angle may be chosen that is found in other respects the most convenient between 20° and 50°. Pine pits and frames are even lower than 20°; but with reference to the supply of light, as well as the descent of the rain, it is not advisable to have the roof flatter than 20°.

Although the necessity of admitting as much light as possible is now generally acknowledged, and although in cloudy weather great advantage will be derived from a roof rendered as transparent as possible, yet the generality of tropical plants do not thrive in bright sunny weather when placed near the glass of a hothouse in this climate; and the necessity of a screen of netting will appear obvious from the effects of solar radiation observed in the tropics as compared with, what is rather surprising, the still greater energy of the same in this country. In the tropics, a thermometer covered with black wool, and consequently prepared to receive the full effects of the sun's rays, does not rise higher than one so exposed in this climate frequently does, notwithstanding the greater general coldness of the air. It is not uncommon in the neighbourhood of London for a thermometer placed in the sun to rise 50° Fahr. above one in the shade. At Cumana, Humboldt never found the sun's rays to have the effect of raising the thermometer more than 6° or 7°. Nearer the pole, the energy of the solar rays appears to be still greater than in this climate. Between lat. 80° and 81°, Captain Scoresby states that the thermometer was 18° below freezing on one side of the ship, whilst on the other the pitch was heated to a temperature of 90° or 100°. This is a greater radiating effect than has perhaps ever been observed in this climate, and certainly unequalled in the tropics. The body of the atmosphere surrounding the earth is supposed to have the form of an oblate spheroid, flattened at the poles and elevated at the equator. Indeed if this were not the case, as it is found to be considerably denser at the poles than at the equator, a different barometrical indication would be the consequence; but at the level of the sea this is everywhere the same. This difference in density may have some effect in weakening the sun's rays, but probably not so much as the circumstance of the atmosphere having a much greater capacity for moisture at the equator than at the poles. At the equator more moisture is required to produce saturation, and at the same time the process of evaporation is so powerful that the atmosphere is maintained on an average much nearer the point of saturation than it is at the poles. These circumstances doubtless contribute greatly to temper the solar rays.

Plants from a great elevation, from within the tropics as well as elsewhere, appear to require less shade than those from the level of the sea. The rays of the sun have been ascertained to be more powerful at 4000 feet above the level of the sea on the mountains of Jamaica than at Port Royal. Hence the potatoe, a native of the high tableland of South America, will not thrive under glass unless placed very near it; and if placed at a distance from it at which the pine-apple, a native of the same country, but near the shore, will grow robust, the potatoe will become pale and languid.

These facts are too important to be omitted in explaining the principles by which the construction of hothouses ought to be regulated, and it will be found that those houses are the most perfectly suited to the cultivation of plants in which such principles have been most considered.

With regard to the means of supplying artificial heat, the old system of using brick flues is now rapidly being superseded by that of hot water. Brick flues occupy a large space; and are also liable to crack and emit sulphureous effluvia to such an extent that the crops of early forcing fruits have often been entirely destroyed. These objections do not apply to hot-water pipes. When once fitted up they require no repairs for many years; whereas the brick flues must be frequently broken up in order to clear out the soot. By hot water the distribution of heat can also be better regulated, and the uniformity of temperature better maintained than by any other known means. The methods of heating by hot water are various. The oldest and perhaps the best for small houses is extremely simple, consisting of a boiler, and, at the further end of the house, a cistern on a level with the boiler. A pipe proceeding from near the top of the boiler, and communicating with the cistern at the same level, conveys the heated water slowly from the former to the latter. Another pipe, situated lower than the preceding, conducts the colder and consequently denser portion of the water from the cistern to the boiler. This is frequently called the return-pipe. A circulation is thus established in consequence of the hottest and therefore the lightest portion of the water ascending, and displacing the colder in the upper pipe, which from its greater density tends to subside at the lowest level, which is in the lower or return pipe. Here it would remain stationary, but the pipe communicating with the water in the boiler, a few inches above the bottom of the latter, and the rarefied water in the boiler being unequal to the balancing of the colder and consequently denser portion in the return-pipe, a continual ingress from the latter takes place into the boiler.

This extremely simple form of the hot-water system has received various modifications. Circulation has been obtained on the siphon principle, the pipes being elevated above the level of the boiler, and a vacuum being formed in them by pumping out or otherwise displacing the air, which is replaced by the water, so that a greater descent is afforded for the water in the return-pipe. Instead of large pipes, of about four inches in diameter, a number of small pipes hermetically closed have also been employed, and coils of such pipes have been inclosed in a furnace instead of a boiler; a large extent of radiating surface is thus made to inclose a comparatively small quantity of water. As the water becomes heated, a degree of pressure corresponding with its expansion takes place; this, however, requires to be regulated by an expansion-tube to prevent explosion. Steam forced through pipes has also been extensively used as a heating agent. Such modes undoubtedly afford the means of raising the temperature more rapidly, and their application in some cases may be attended with advantage; but as the cooling, if the fuel be not supplied regularly, takes place in the same ratio of rapidity, it becomes a question whether a mode that produces a slow and lasting heat, or one that is rapid in its production and decline, is to be preferred. In order to solve this, it becomes necessary to take into consideration the progressive amount of heat which is required in hothouses relative to time. At noon, or soon after, the natural temperature of this climate is generally at the highest, and the temperature of the hothouse should also then be higher than at any other time of the day or night. The external temperature declines gradually till three or four A.M., when it reaches its minimum, of perhaps 50° below the noon temperature. The hothouse temperature should in like manner gradually decline, but only to the extent of between 5° and 10°. It is therefore evident that artificial heat must be increased, if well applied, so as exactly to make up the deficiency; and it should by no means be allowed to have any more than one rise and fall in the course of twenty-four hours. By a rapidly heating apparatus, this is next to impossible; and independently of all other inconveniences, sudden changes of temperature are sure to affect the hygrometrical state of the air in the house, causing condensation and consequent dryness. A slow but effective and lasting heating power is therefore preferable.

Only a very few modifications of the plan of heating by hot water require to be adverted to in this place. Instead of the pipes running quite horizontally from the boiler to the cistern, they may be slightly elevated towards the latter, which has the effect of conveying a greater proportion of the heat to the part of the house which is most remote from the boiler. The boiler must be so constructed and placed as to admit of the water contained in it being a little higher than the most elevated portion of the upper pipe. Flat pipes are sometimes employed as upper ones. As their transverse section is a parallelogram, and as a circle contains more space than any other figure of equal perimeter, these flat pipes contain less water in proportion to their surface, and consequently the water in them is sooner heated to its maximum; but this, as previously shown, is no advantage, if in fact it be not a disadvantage, since it cools so much sooner.

With regard to a supply of moisture, the above hot-water system, in which the pipes are level, or nearly so, presents several advantages over other methods of heating. Troughs can be arranged along the whole length of the pipe, which, when filled with water, will produce a gentle but constant evaporation. Besides the supply from this source, a large quantity of steam may be safely introduced from the boiler, provided the violence of its ingress be a little broken by a perforated sheet of metal, or any similar contrivance. Another source of moisture is supplied by the reservoir, which, with moisture from the soil in which the plants are grown, and from the wetted floors, ought to keep the atmosphere of the house sufficiently moist during the night. The elasticity, however, of the vapour will be very great, particularly in cold nights when much fire heat is required; and in such a state of the weather the condensation from the coldness of the glass will be increased. The atmosphere of the house is not only deprived of its moisture by this process, but a serious loss of heat by radiation from the glass takes place at the same time. This loss of heat and transmutation of moisture resulting from the radiation of the glass, although little attended to, demands the most serious care. It admits of no remedy but the interposition of some medium between the glass and cold sky; and such substances as are the worst conductors of caloric, and which will also keep the glass dry, are of course the best. A woollen net mounted on a roller, with pulleys attached, would have a very beneficial effect if closely covered by light wooden shutters or a tarpaulin. And as it has been proved that the rays of the sun are frequently too powerful for hothouse vegetation, the netting would likewise be occasionally very useful as a shade; and with this provision the roof cannot be made too transparent, as previously stated.

It has been shown that iron roofs occasion an obstruction of light to the extent of only one-third of that which takes place when wood is employed. The iron roofs are therefore preferable, although, apart from the greater original expense, there are still some objections to them. Formerly the chief objection was the breakage of glass likely to result from the expansion of the metal; but the severity of the frost in 1838 has proved that this objection was groundless, for very little breakage occurred in the iron roofs compared with what took place in wooden ones; and it may be fairly asserted that none whatever was broken from contraction of the metal; nor can any breakage take place from its expansion if the glazing is performed in summer, or the glass cut so as to fit in with ease, or the panes made one-thousandth part of an inch less than the bed between the rebates of the bars in which they are placed. The principal remaining objection is that of the rapid abduction of heat. Plants never do thrive so well in the proximity of iron as in that of wood, and this is probably owing to the wood being a slower conductor of caloric. Supposing a bar of iron is heated to 100° by the sun's rays, and then syringed with water, it will instantly become very cold, in consequence of evaporation; and if any plant be in contact with it, or nearly so, the juices will experience a chill. In many instances, therefore, where plants require to be close to the glass, such as in propagating houses and pits, wood is certainly preferable to iron. Again, when a wide and also lofty house is to be glazed, iron is more proper; for besides the quantity of rays lost by reflection of glass and obstruction from rafters, those that do pass into the interior are so weakened, that when they reach vegetation remote from the glass they do not appear to be effective in performing the requisite functions in a perfect manner; but of course better when the roof is of iron than when wood is employed.

Various modes of ventilation are in use. One which was considered a great improvement has not been found to be so,—namely, the having ventilators in front at the lower angle, and corresponding ones in the back wall near the top inside, communicating with the external air by means of openings in the south side of the parapet. Sometimes this mode appears to have little effect, and the temperature ascends too high, till the movement of a slight breeze outside causes instantly a rush of cold air. Ventilation should be so contrived as to be sufficiently effective in preventing excess of heat; but at the same time it should be perfectly at command, so that it may be employed when requisite in the most limited degree. No method should be finally adopted until it is put to the test by trying whether, under any agitation of the external air, a candle will burn steadily inside if placed near the apertures by which the air is admitted.

In all forcing-houses tanks should be placed for supplying water of a temperature more suitable to the nature of the vegetation than that from a pump out of doors. Nothing can be more injurious than cold water applied to the roots and tops of tropical plants, or others in a forcing state under a high temperature. The rain and dews which supply the plants of warm climates cannot be much below the mean temperature of the climate; and if only equal to the minimum, still it would be between 20° and 30° above that of spring-water in Britain.

To these general remarks upon the principles of constructing hothouses, a few observations of detail require to be added. Greenhouses and conservatories are commonly included in the appellation of hothouse. The only difference between them is, that fires are seldom used in the greenhouse unless in very severe weather, while the hothouse is constantly kept at a high temperature; but so far as the building is concerned, they may be considered as the same. A greenhouse is for keeping and growing the plants of temperate countries; while a hothouse is used for forcing fruits, or for growing plants which are indigenous to tropical regions. Hothouses may be classed under four different heads,—namely, the *dry stove*, the *damp stove*, the *bark stove*, and the *forcing-house*.

The *dry stove*, as the name implies, is used for the cultivation of plants which do not require much water; such as the different species of Cacti, some Euphorbias, and other Succulents of like habits. The management of such a house is very simple. The temperature during the winter months should never exceed 55° of Fahr. No water should ever be given at that period, unless the plants show signs of suffering from want of it; indeed very little water should be given at any season, except when the plants are growing. In spring, or early in summer, most of the plants will show an inclination for growth, and then they may be watered about twice a week, but this must be done with great caution, otherwise they are very apt to rot. During summer fires may be discontinued, and plenty of air given in fine weather. The plants will probably get covered with dust and will be unsightly; in this case they may be syringed, but caution must be used in doing this, especially with melon-shaped Cacti, as the water lodges in their hollow tops, and eventually destroys them, if allowed to remain.
